Foreword

“Enthusiasm is a driving force that overcomes all obstacles”

It is my proud privilege to write a foreword for second edition of this book by Dr Anil Ghom. In short time, this book has become most popular among undergraduates and postgraduates all over the country.

In the second edition, numbers of chapters have been presented in a better organized manner. This book carries updated information of the subject in this rapidly changing world of science. A new chapter “Controversial Diseases and Terminologies” is incorporated, also there are large number of new photographs, radiographs, MCQs and references. I am sure this new updated second edition will be more beneficial for the undergraduate and postgraduate students for reference and regular reading.

RN Mody

Professor and Head
Department of Oral Medicine and Radiology
Hitkarini Dental College
Jabalpur, MP

Preface to the Second Edition

'We become strong only after we have acknowledged our weakness. Gather knowledge, insight, and experience and then make your own decision'

This is the second edition of the textbook and I am gratified by the acceptance and support that the book has received over the years from educators, students and practitioners. The purpose of second edition of this book is two-fold. First, to include what is new and recent knowledge and the second is correct shortcoming of the first edition. I have evaluated and utilized suggestions from all the critical reviews and recommendations from the faculty members.

Obviously, each successive edition of textbook finds the edition with more information. So in this edition I have attempted to solidify and include recent knowledge. This book also includes a new Chapter *Controversial Diseases and Terminologies*. Purpose of this chapter is that as knowledge is changing everyday with advanced diagnostic techniques, many old terminologies are discarded and new one are introduced.

My first book was criticized a lot for not including references and not having enough photographs in the book. So in this second edition I have included references and around 1000 photographs/illustrations for easy understanding of the diseases.

MCQs chapter is completely revised and all the new MCQs are added at the end of chapter. I have also included diagnosis of each lesion in diseases, so that students can understand key point in disease and they can easily remember it.

Again, as a human being, mistakes are bound to happen. I tried this second edition to best of my efforts, still there can be shortcoming and I request readers to make note of it and I will try to rectify it in the next edition.

Anil Govindrao Ghom
sanvil@rediffmail.com
anil_ghom@yahoo.com

Preface to the First Edition

"You must not be discouraged if the world does not rush to you, demanding what you have; neither must you quietly sit down to let world wonder and then seek you; you must be aggressive, you must carry your truths to people and cause them to see them so clearly that they must accept them"

The student looked for a reference on which to build an educational foundation with regard to basic principle. A few years ago much of the information offered in this text was not available.

Since the principle and treatment modalities offered herein will continue to evolve, it behooves the student to be fully informed of the state-of-art to be able to critically evaluate the worthiness or applicability of any future development.

I have endeavored to ensure that a consistent style has emerged and is in harmony where appropriate with the diseases of oral region along with the differential diagnoses which are covered in detail.

The purpose of this book is to correlate the gross and microscopic pathological features with the radiographic appearance of oral diseases and systemic diseases manifested in the jaw.

In our increasingly litigious society, it is vital that the dentist understands the law as it relates to dentistry. The Chapter on Medicolegal Issue is Essential Reading, along with the Consumer Protection Act.

Diseases can be understood best when the interpreter understands not only the disease process but also the basic science associated with it. For this reason, I have included separate section for basic science.

Recently, as exam pattern is changing and MCQs are getting importance, MCQs are added in separate chapter.

I tried my best, to cover all the aspects of oral diseases in my book. If this goal is achieved, then this textbook may contribute, in a small way to better care of patients who suffer from these diseases.

Anil Govindrao Ghom

Acknowledgements

‘The man who really wants to do something finds a way, the other finds an excuse’

No work will be complete without help of your friends and well wishers and I am lucky to have them with me in this venture.

First of all, I am immensely thankful to Dr Vaishali Gawande for her untiredly help in completion of this project. My special thanks to Dr Neeta Wasnik and Dr Anjusha Ganar who helped me a lot.

I am also thankful to Dr Swapnil Diwakirti for her help in preparation of diagrams in the book. I am thankful to all the contributors for their contribution in this book.

My sincere thanks to Dr Pravin Lambade, Dr Jitendra Sachdeo, Dr Vikas Meshram, Dr Bhaskar Patle, Dr Revant Chole, Dr Amit Parate, Dr Sanjay Pincha, Dr Milind Chandurkar, Dr Ashok L, Dr Umaraji, Dr Tapasya Karemore, Dr Avinash Kshar, Dr M Shimizu, Dr Fusun Yasar, Dr Iswar, Dr Bande, Dr Kadam, Dr R Kamikawa, Dr FM Debta and Dr Suwas Darvekar for providing clinical and radiological photographs in the book.

Beauty is God’s gift but to utilize it in proper direction is in your hand. I am thankful to all those beautiful faces in book— Dr Gagandeep Chawala, Dr Smiriti Goswami, Dr Uma Rohra, Dr Swapnil Dewakirti, and Dr Pragya Jaiswal.

I would like to thank Dr Ranit Chhabra, Dr Priyanka Aggarwal, Dr Shaheen Hamdani, Dr Payal Tapadiya, and Dr Vivek Lath for their help in proofreading.

I offer my humble gratitude to my guide Dr RN Mody for his guidance during my postgraduation and after post-graduation.

Friends are always big supporters so I am grateful to Dr Pravin Sundarkar, Dr Neeraj Alladwar and Dr Ravindra Govindwar for heartily wishes. I am also thankful to my brothers and sisters especially elder brother Sadanand for their moral support in my life.

I am thankful to Shri Jitendar P Vij (Chairman and Managing Director) and Mr Tarun Duneja (Director-Publishing) of M/s Jaypee Brothers Medical Publishers (P) Ltd., for publishing this book. Commendable type setting, proofreading and improvement in illustrations have been done respectively by Ms Sunita Katla, Md Shakiluzzaman & Ms Geeta Srivastava and Mr Sumit Kumar.

Whenever I think who completely changes my life is my wife Savita, who is there in my thick and thin. Whenever I am down, she is there to uplift me with her prayer and support. She is a person with generous heart and I am thankful to God to give gift like her to me in my life.

Lastly, I offer my earnest prayers to the Almighty for endowing me the strength and confidence in accomplishing to the best of my abilities.

Basics

Oral Diseases: An Introduction

The ultimate aim of entire dental education is to see how well it prepares the practitioners to serve patients. If one has to be a good practitioner it is essential to have a thorough understanding of the basic sciences related to dentistry.

Stomatology is the science of structure, function, and disease of the oral cavity. Study methods include examination of related histories, evaluation of clinical signs and symptoms and use of biochemical, microscopic and radiological procedures to establish a diagnosis and a plan for therapeutic management.

Diagnosis is the process of evaluating patient's health as well as the resulting opinions formulated by the clinician. *Oral diagnosis* is the art of using scientific knowledge to identify oral disease processes and to distinguish one disease from another.

History of oral medicine starts when *William Gies* of Columbia University in 1926 recommend that oral medicine topics should be covered in dental curriculum. In 1945, the American Academy of Oral Medicine was formed. Oral medicine definition accepted in 1993 by international association of oral medicine. It states that —

'Oral medicine is that area of special competence in dentistry concerned with diseases involving the oral and paraoral structures. It includes the principles of medicine that relate to the mouth as well as research in biological, pathological, and clinical spheres. Oral medicine also includes the diagnosis and medical management of diseases specific to the orofacial tissues and oral manifestations of systemic diseases. It further includes the management of behavioral disorders, the oral and dental treatment of medically compromised patients'.

It can also be defined as 'diagnosis and treatment of oral lesions as well as non-surgical management of temporomandibular joint disorders and facial pain and dental treatment for medically compromised patients in an outpatient sitting, or in an inpatient sitting under general

anesthesia, including specialty care in periodontics and endodontic'.

The goal and objective of oral medicine are discussed below. The goal is to provide education, research and service for health care professionals and the public.

- *Education*—it consists of predoctoral, postdoctoral and continuing education training for the health care professional.
- *Research*—it includes activities in the field of biology as it is related to oral disease.
- *Service*—service to society and health care professionals is the objective of oral medicine. Oral medicine will train the professional to provide current and future patient care.

As nowadays, epidemiology is changing, in the future, oral medicine person has to come across many oral diseases and he has to diagnose them. World Health Organization in 1989 study called 'trends in oral health care, a global perspective' told that in future greater role is required by the oral medicine professional.

In the field of oral medicine, you should have a basic understanding of various diseases and their impact on oral tissue, so that it is easy for a practitioner to recognize the presence of any major systemic diseases and then accordingly make the correct diagnosis and treatment plan so as to do thorough justice of what is happening to him.

The field of oral medicine consists chiefly of the diagnosis and medical management of the patients with complex medical disorders involving the oral mucosa and salivary glands as well as orofacial pain and temporomandibular joint disorders. Specialists trained in oral medicine also provide dental and oral health care for patients with medical diseases that affect dental treatment, including patients receiving treatment for cancer, diabetes, cardiovascular diseases, and infectious diseases (**Fig. 1-1**).

Oral medicine practice provides physical and medical evaluation, head and neck examination, laboratory

analysis, oral diagnosis and oral therapeutics for such conditions as: vesiculobullous, ulcerative mucosal diseases, painful and burning mucosa, infectious oral diseases, oral conditions arising from medical treatment, oral manifestations of systemic diseases and salivary gland dysfunction.

The specialist will perform a comprehensive and/or specialized examination, provide consultation, possibly perform and interpret laboratory tests and perform or prescribe treatments or make the appropriate referrals.

Fig. 1-1: Diagrammatic representation of different areas of oral medicine showing branches and goal of oral medicine.

Dental management of medically compromised patients is becoming a routine and increasingly important part of dental practice. Several factors contribute to this phenomenon. First, the population continues to age. Many older patients have multiple medical conditions. Second, as medical care becomes more effective and cost issues are emphasized, many patients are being treated on an ambulatory basis to avoid hospitalization. Consequently, these individuals are in the community and readily seek dental care. Third, the sophistication of medical treatment is prolonging life. And fourth, the level of and access to available dental care has improved, resulting in more patients (regardless of medical status) wanting dental treatment. Therefore, behavior disorders and diseases of the mouth as manifestations of systemic disease are seen at an increasing rate, and require prompt and adequate care by experienced specialists.

Philosophically and in practice, dentistry is similar to one of the various specialties of medicine and consequently,

it is imperative that the dentist understands the medical background of patients before beginning dental therapy, which might fail because of the patients compromised medical status or result in morbidity or death of the patients.

The dentist trained in oral medicine should be philosophically atuned to the patient and have knowledge of medically important diseases as well as of dental problems. The dentist should be well versed in the use of rational approaches in diagnosis, medical risk assessment and treatment.

The hospital is frequently the setting for the most complex cases in oral medicine. Hospitalized patients are most likely to have oral or dental complications of bone marrow transplantation, hematological malignancies, poorly controlled diabetes, major bleeding disorders, and advanced heart disease. The hospital that wishes to provide the highest level of care for its patients must have a dental department.

The hospital dental department should serve as a community referral center by providing the highest level of dental treatment for patients with severe systemic disease and management of the most medically complex patients is best performed in the hospital because of the availability of sophisticated, diagnostic and life-sustaining equipment and the proximity of expert consultants in all areas of health care.

Most difficult and unusual problems evaluated by the dentist are seen as consultations. To handle consultations properly, the dentist must be familiar with the proper method of requesting and answering consultations.

The role of imaging in oral medicine varies greatly with the type of problem being evaluated. Certain problems, such as pain in the orofacial region, frequently require imaging to determine the origin of the pain. For other conditions, however, such as soft-tissue lesions of the oral mucosa, imaging offers no new diagnostic information.

Thus, to conclude oral medicine expert is an important professional in dental and medical team of nations health care scheme to public. Oral medicine personal is also expert in studying, diagnosing and treating the mouth disease.

Development and Eruption of Teeth

Introduction

Development of tooth is a result of complex process occurring between oral epithelium and underlying mesenchymal tissue. The primitive cavity is lined by stratified squamous epithelium, i.e. oral ectoderm, which contacts the endoderm of foregut to form the buccopharyngeal membrane. At 27th day of gestation, this membrane ruptures and primitive oral cavity establishes a connection with the foregut.

The scale of human tooth development:

- 42-48 days—dental lamina formation.
- 55-56 days—bud stage—deciduous incisor, canine and molar.
- 14th week—bell stage for deciduous bud for permanent.
- 18th week—dentin and functional ameloblast.
- 32nd week—dentin and functional ameloblasts of permanent 1st molar.

Stages of Tooth Development

Dental Lamina Formation

- *Proliferation of basal cells*—proliferation of certain areas of basal cells of the oral ectoderm occurs more rapidly than cells of adjacent area. This will result in formation of dental lamina. Dental lamina is a band of epithelium which has invaded underlying ectomesenchyme along each of the horseshoe shaped future dental arch (**Fig. 2-1**).
- *Time taken for dental lamina formation*—total activity of dental lamina formation extends at least over a period of 5 years. The remnants of dental lamina persist as epithelial pearls or islands within the jaw as well as in the gingiva.
- *Successional lamina*—the lingual extension of dental lamina is called as successional lamina.

Fig. 2-1: Schematic diagram showing initiation of dental lamina by some proliferating basal cells.

Bud Stage (Initiation)

- *Primordia of enamel organ*—after the differentiation of dental lamina, round or ovoid swellings arise from basement membrane. This arises at 10 different points which corresponds to the future position of deciduous teeth. These are primordia of the enamel organs, the tooth bud.
- *Enamel organ*—the enamel organ consists of peripherally located low columnar cells and centrally located polygonal cells.
- *Dental papilla*—the area of ectomesenchymal condensation immediately adjacent to enamel organ is called as 'dental papilla'. Cells of dental papilla form future tooth pulp and dentin (**Fig. 2-2**).
- *Dental sac*—the condensed ectomesenchyme that surrounds the tooth bud and dental papilla is called as a 'dental sac'. Cells of dental sac form cementum and periodontal ligament.

Fig. 2-2: Diagram of bud stage showing dental lamina and dental papilla formation (ectomesenchyme condensation).

Cap Stage (Proliferation)

- **Proliferation**—as the tooth bud continues to proliferate, there is unequal growth in different parts of the tooth bud, which leads to cap stage, which is characterized by shallow invagination on the deep surface of bud.
- **Enamel epithelium**—the peripheral cells of the cap, which cover the convexity is called as 'outer enamel epithelium' which is cuboidal cells and cells of concavity are called 'inner enamel epithelium' which is tall columnar cells (Fig. 2-3).
- **Stellate reticulum**—stellate reticulum is located between outer and inner enamel epithelium, which assume a reticular form. The space in this reticular network is filled with mucoïd fluid (rich in albumin) which gives it a 'cushion-like' consistency. Due to this, stellate reticulum supports and protects the delicate enamel-forming cells.

Fig. 2-3: Inner enamel epithelium cells further differentiate into ameloblasts. It also shows outer enamel epithelium (red arrow) and stellate reticulum (yellow arrow).

Bell Stage (Histodifferentiation and Morphodifferentiation)

- **Types of cell present**—as the invagination of epithelium deepens and its margins continue to grow; the enamel organ assumes 'a bell shape'. Four different types of cell i.e. cells of inner enamel epithelium, stratum intermedium, stellate reticulum and outer enamel epithelium are present (Fig. 2-4).
- **Cells of inner enamel epithelium**—it is single layer of tall columnar cells. The cells of inner enamel epithelium differentiate into ameloblast prior to amelogenesis. The cells of inner enamel epithelium exert an organizing influence on the underlying mesenchymal cells in dental papilla, which then differentiate into odontoblasts.
- **Stratum intermedium**—it is the squamous cells occurring between inner enamel epithelium and stellate reticulum.
- **Stellate reticulum**—these cells are star shaped. It has long process and it anastomoses with process of adjacent cells.
- **Outer enamel epithelium**—these are single layered cuboidal cells.
- **Enamel knot**—the cells in the center of the enamel organ are densely packed and form the enamel knot.
- **Enamel cord**—this is the vertical extension of the enamel knot. These cells are attached to one another by junctional complex laterally and to cells in stratum intermedium by desmosomes.
- **Membrana preformativa**—the basement membrane that separates the enamel organ and dental papilla just before dentin formation is called as 'membrana preformativa'.

Fig. 2-4: Bell stage showing four different types of cells.

Advanced Bell Stage

- **Dentinoenamel junction**—during the advanced bell stage, the boundary between inner enamel epithelium and odontoblasts outline the future dentino-enamel junction.
- **Epithelial root sheath of Hertwig's**—in addition, cervical portion of enamel organ gives rise to epithelial root sheath of Hertwig's (Fig. 2-5).

Fig. 2-5: Advanced bell stage showing root sheath of Hertwig's.

Eruption of Teeth

The axial or occlusal movement of tooth from its developmental position within the jaw to its functional position in the occlusal plane is known as *eruption of teeth*. There are 3 types of movements which are described as follows:

Pre-eruptive

- **Crowding of teeth**—when deciduous tooth germ first differentiates, there is good deal of space between them. But due to their rapid growth, this available space is utilized and developing teeth become crowded together, especially in incisor and canine region (Fig. 2-6).
- **Drifting of deciduous molar**—crowding is relieved by growth in length of infant's jaws, which provides room for second deciduous molars to drift backward and anterior teeth to drift forward. At the same time, the tooth germ also moves outward as jaw increases in width and height (Fig. 2-6).
- **Movement of permanent teeth**—permanent teeth with deciduous predecessors also undergo complete movement before they reach the position from which they will erupt (Fig. 2-6).
- **Eruption of deciduous predecessor teeth**—as their deciduous predecessors erupt, they move to a more apical position and occupy their own bony crypt.
- **Permanent premolars**—premolars begin their development lingual to their predecessors at the level of occlusal surface. They are situated beneath the divergent roots of deciduous molars.
- **Permanent molar**—the permanent molars which do not have predecessors also move from the site of their initial differentiation.

Eruptive

- **Axial movement**—there is axial or occlusal movement of tooth from its developmental position within the jaw to

Fig. 2-6: Diagrammatic representation of pre-eruptive phase of eruption.

its final functional position in the occlusal plane. It is important to recognize that jaw growth is normally occurring while most of the teeth are erupting, so that movement in plane other than axial is superimposed on eruptive movement (Figs 2-7 and 2-8).

Fig. 2-7: Diagrammatic representation of eruptive phase of eruption.

Fig. 2-8: Eruptive phase of eruption of teeth showing root resorption of deciduous molar.

Posteruptive

- **Maintenance**—it maintain the position of the erupted tooth while the jaw continued to grow.

Chronology of eruption of teeth				
Deciduous dentition				
Tooth	Formation of enamel matrix and dentin begins	Enamel completed	Eruption	Root completed
Upper				
Central incisor	4 months <i>in utero</i>	1½ months	7½ months	1½ years
Lateral incisor	4½ months <i>in utero</i>	2½ months	9 months	2 years
Cuspid	5 months <i>in utero</i>	9 months	18 months	3½ years
First molar	5 months <i>in utero</i>	6 months	14 months	2½ years
Second molar	6 months <i>in utero</i>	11 months	24 months	3 years
Lower				
Central incisor	4½ months <i>in utero</i>	2½ months	6 months	1½ years
Lateral incisor	4½ months <i>in utero</i>	3 months	7 months	1½ years
Cuspid	5 months <i>in utero</i>	9 months	16 months	3¼ years
First molar	5 months <i>in utero</i>	5½ months	12 months	2¼ years
Second molar	6 months <i>in utero</i>	10 months	20 months	3 years
Permanent dentition				
Tooth	First evidence of calcification	Crown completed	Eruption	Root completed
Upper				
Central incisor	3-4 months	4-5 years	7-8 years	10 years
Lateral incisor	10 months	4-5 years	8-9 years	11 years
Canine	3 years	6-7 years	11-12 years	13-15 years
First premolar	1½ - 1¾ years	5-6 years	10-11 years	12-13 years
Second premolar	2-2¼ years	6-7 years	10-12 years	12-14 years
1st molar	At birth	2½ - 3 years	6-7 years	9-10 years
2nd molar	2½ - 3 years	7-8 years	12-13 years	14-16 years
3rd molar	7-9 years	12-16 years	17-21 years	18-25 years
Lower				
Central incisor	3-4 months	4-5 years	6-7 years	9 years
Lateral incisor	3-4 months	4-5 years	7-8 years	10 years
Canine	4-5 months	6-7 years	9-10 years	12-14 years
1st pre molar	1¾ - 2 years	5-6 years	10-12 years	12-13 years
2nd pre molar	2¼ - 2½ years	6-7 years	10-12 years	13-14 years
1st molar	At birth	2½ - 3 years	6-7 years	9-10 years
2nd molar	2½ - 3 years	7-8 years	11-13 years	13-15 years
3rd molar	8-10 years	12-16 years	12-21 years	18-25 years

- *Compensatory growth*—it compensates for proximal and occlusal wear (Fig. 2-9).

Fig. 2-9: Diagrammatic representation of post-eruptive phase of eruption.

Development and Anatomy of Craniofacial Region

3

Oral Cavity Development

The primitive oral cavity is seen in third prenatal week. There is formation of pit in the tissue which underlies the forebrain. This pit is the future oral cavity. The formation of branchial arches occurs on either side of fetal neck, between the oral pit and developing heart. The process of development of oral cavity is as follows:

- *Invagination*—it occurs between forebrain and heart. Oral cavity forms under the forebrain.
- *Formation of oropharyngeal membrane*—this is wall formed between oral and pharyngeal cavity. It separates the stomodium from first part of foregut. Foregut will develop into pharynx.
- *Disintegration of oropharyngeal membrane*—in fourth week of intrauterine life, oropharyngeal membrane disintegrates. This will lead to continuity between oral and pharyngeal cavity.
- *Formation of endocrine gland*—endocrine glands can develop from roof and floor of oral cavity. Roof gives rise to Rathke's pouch, which results in the formation of anterior pituitary. Floor can give rise to second epithelial pouch which results in formation of endocrine tissues of the thyroid gland.
- *Formation of branchial arch*—tissues which surround the oral pit give rise to five to six pairs of branchial arch. The mandibular branchial arch is first arch to develop. The hyoid is second arch to develop. Other three arches are not so important in dental point of view.
- *Vestibule*—it is outer smaller portions of oral cavity. Vestibule of the mouth is a narrow space bounded externally by lips and cheeks and internally by teeth and gums.
- *Oral cavity proper*—it is inner larger part of oral cavity. It is bounded anterolaterally by the teeth, the gums and the alveolar arches of the jaws. The roof is formed by the hard and soft palate. The floor is occupied by the tongue posteriorly and sublingual region anteriorly, below the tip of tongue. Posteriorly, the cavity communicates with the pharynx through the oropharyngeal isthmus which is bounded superiorly by the soft palate, inferiorly by the tongue and on each side by the palatoglossal arches.
- *Arterial and venous supply of face*—arterial and venous supply is showing in **Figs 3-1 and 3-2**.

Vestibule

Lips

It is described in the Chapter 23: Disease of Lip.

Cheeks

- *Content*—cheeks are the fleshy flaps, forming a large part of the sides of the face. Mobile portion of cheeks is formed by the buccinator muscle. Intraorally, it is covered by the mucous membrane, and extraorally by the skin. The mucous membrane of the cheeks is fixed to the inner fascia of the buccinator muscle by tight strands of connective tissue.
- *Posterior part*—posterior part consist of masseter muscle and the parotid gland which are interposed between the mucous membrane and buccinator muscle on one side and the skin on the other side.
- *Nasolabial sulcus*—cheek are continuous in front with the lips and the junction is indicated by the *nasolabial sulcus* which extends from the side of nose to the angle of the mouth.

Anatomy of Oral Cavity

The oral cavity is incompletely bounded by bones. Its lateral and anterior walls are formed by the inner surface of the alveolar processes, which join at the midline. The lingual surface of the teeth completes these walls. Oral cavity is divided into:

- *Buccal fat pad of Bichet*—the cheek contains a peculiar body of fat tissue called as *buccal fat pad of Bichet*. It is rounded biconvex structure limited by a thin but distinctive capsule.
- *Blood supply*—it is supplied by the branches of the maxillary artery (Fig. 3-1).
- *Lymphatic drainage*—drain into the submandibular and pre-auricular lymph nodes and partly to the buccal and mandibular nodes.

Fig. 3-1: Arterial supply of the face.

Oral Cavity Proper

Gingiva

It is described in the Chapter 24: Gingival and Periodontal Diseases.

Teeth

- *Structure*—the teeth form a part of the masticatory apparatus and are fixed to the jaws. In man, the teeth are replaced only once (*diphyodont*) in contrast with non-mammalian vertebrates where teeth are constantly replaced throughout life (*polyphyodont*). Each tooth has three parts, i.e. crown (projection above the gums), root (embedded in the jaw beneath the gum) and neck (between the crown and root and surrounded by the gums).
- *Nerve supply*—it is supplied by *anterior superior alveolar* (upper incisor and canine teeth), *middle superior alveolar* (upper premolar teeth), *posterior superior alveolar* (molar teeth) and *inferior alveolar nerve* (lower teeth).
- *Blood supply*—it is supplied by *posterior superior alveolar artery* (molar and premolar maxillary teeth), *anterior superior alveolar* (It is branch of infraorbital artery and supplies incisor and canine maxillary teeth) and *inferior alveolar artery* (it enters the mandibular canal and gives branches to the mandible and to the roots of each teeth attached to the bone).

Hard Palate

- *Development*—this is the tissue which is interposed between oral and nasal cavity. Palate develops from medial and lateral palatine process. Development of palate starts in sixth week. It develops as intermaxillary segment, between maxillary process of upper jaw. This is called as primary palate. At the end of sixth week, secondary palate develops from lateral palatine process. Lateral palatine process grows medially downward or vertically on either side of tongue.
- *Boundaries*—it is a partition between the nasal and oral cavities. Anterolateral margins are limited by alveolar arches and gingiva. Posterior margin is continuous with the soft palate. Superior surface forms the floor of the nose and inferior surface forms the roof of the oral cavity.
- *Nerve supply*—it is supplied by greater palatine nerves from the greater palatine foramen and nasopalatine nerve from the incisive foramen.
- *Blood supply*—it is supplied by greater palatine branch of the maxillary artery and nasopalatine artery.
- *Venous drainage*—palatine vessels go to the pterygoid plexus of veins.
- *Lymphatic drainage*—it drains mostly into the upper cervical and partly into the retropharyngeal groups of nodes.

Soft Palate

- *Content*—it is a movable fold suspended from the posterior border of the hard palate. It separates the nasopharynx from the oropharynx. It has two surfaces, i.e. anterior and posterior and two borders, i.e. superior and inferior.
- *Anterior surface*—it is concave and is marked by median raphe.
- *Posterior surface*—it is convex and is continuous superiorly with the floor of the nasal cavity.
- *Superior border*—it is attached to the posterior border of the hard palate, blending on each side with pharynx.
- *Inferior border*—it is free and bounds with pharyngeal isthmus.
- *Muscle of the soft palate*—these are tensor palati, levator palati, musculus uvula, palatoglossal and palatopharyngeus.
- *Nerve supply*—all muscle of the soft palate except the tensor palati are supplied by the pharyngeal plexus. The fibers of the plexus are derived from the cranial part of the accessory nerve. The tensor palati is supplied by mandibular nerve. General sensory nerves are derived from lesser palatine nerve.
- *Blood supply*—greater palatine branch of the maxillary artery, ascending palatine branch of facial and palatine branch of ascending pharyngeal arteries.

- *Venous drainage*—veins pass to the pterygoid and tonsillar plexus of veins.
- *Lymphatic drainage*—lymphatics drain into upper cervical and retropharyngeal lymph nodes.

Tongue

It is described in the Chapter 22: Diseases of Tongue.

Floor of Mouth

- *Content*—it is a crescent shaped area between the lower gingiva and undersurface of the tongue which composes the inferior most portion of the oral cavity overlying the mylohyoid and thyroglossal muscles.
- *Nerve supply*—it is supplied by the branches of trigeminal nerve.
- *Arterial supply*—it is supplied by facial artery.
- *Venous drainage*—drains into facial or lingual vein (**Fig. 3-2**).
- *Lymphatic drainage*—from the anterior portion of mouth, lymphatics may pass into the deep cervical nodes or laterally to the periosteal lymphatics and then to the submandibular nodes and goes to the deep internal jugular nodes.

Fig. 3-2: Venous supply of the face.

Maxillary Sinus

It is described in the Chapter 27: Disorders of Maxillary Sinus.

Salivary Glands

It is described in the Chapter 26: Disorders of Salivary Glands.

Pharynx

- *Development*—muscles of pharynx are formed at about 7th week of intrauterine life. It forms from the muscle

cell of third and fourth arches. It forms the stylopharyngeal, cricothyroid, levator palatine and constrictor muscle of the pharynx.

- *Content*—it is a wide muscular tube situated behind the nose, mouth and larynx. Clinically, it is a part of upper respiratory tract. It is divided into three parts, i.e. nasopharynx (nasal part of pharynx), laryngopharynx (laryngeal part of pharynx) and oropharynx (oral part of pharynx). Oropharynx is the middle part of the pharynx situated behind the oral cavity.
- *Blood supply*—it is supplied by ascending pharyngeal branch of the external carotid artery, ascending palatine and tonsillar branch of the facial artery, dorsal lingual branch of lingual artery and greater palatine, pharyngeal and pterygoid branch of the maxillary artery.
- *Venous drainage*—it is supplied by a plexus which receives blood from the pharynx and soft palate and prevertebral region and drains into the internal jugular and facial veins.
- *Lymphatic drainage*—it drains into the retropharyngeal and deep cervical lymph nodes.
- *Nerve supply*—it is supplied by the pharyngeal plexus of nerves which lies chiefly on the middle constrictor.

Muscles of Mastication

The muscles of mastication move the mandible during mastication and speech. They are the masseter, the temporalis, the lateral pterygoid and the medial pterygoid.

Development

- *Proliferation of myoblasts*—muscles of mastication are derived from mandibular arch, i.e. first branchial arch. In fifth and sixth week of intrauterine life, proliferation of myoblasts occurs.
- *Orientation of muscle cells*—muscle cells become oriented to the sites of origin and insertion.
- *Migration*—enlargement of muscle mass occurs and it will migrate into the areas of differentiation.
- *Formation of muscles*—after this, it will be differentiated into masseter, medial and lateral pterygoid and temporal muscle. By tenth prenatal week, muscle mass becomes well organized. Muscle cells of masseter and medial pterygoid form vertical lob which is inserted at angle of mandible. Fibers of lateral pterygoid go horizontally and insert in the articular disc. The temporalis muscle has differentiated in the infratemporal fossa and is inserted in the coronoid process (**Fig. 3-3**).
- *Innervations of facial muscle*—in seventh week, fifth nerve enters the mandibular arch and seventh nerve in second branchial arch.

Fig. 3-3: Muscle of mastication—A diagrammatic representation.

Masseter Muscle

- **Site**—it is the most superficial to the masticatory muscle, stretches as a rectangular plate from the zygomatic arch to the outer surface of the mandible. It has three layers i.e. superficial, middle and deep.
- **Superficial layer**—it arises by thick aponeurosis from the zygomatic process of the maxilla and from the anterior two-third of the lower border of zygomatic arch. Its fibers pass downward and backward to be inserted into the angle and lower half of lateral surface of ramus of mandible (Fig. 3-4).
- **Middle layer**—it arises from the deep surface of the anterior two-third of the zygomatic arch and posterior one-third of lower border of zygomatic arch and is inserted into middle of ramus of mandible.
- **Deep layer**—it arises from deep surface of the zygomatic arch and is inserted into upper part of the ramus of the mandible and into the coronoid process.
- **Nerve supply**—it is supplied by masseteric nerve which is a branch of anterior division of the mandibular nerve.
- **Blood supply**—the masseteric artery which is a branch of internal maxillary artery and the masseteric vein follow the course of the nerve.

Fig. 3-4: Origin and insertion of masseter muscle.

- **Functions**—its main function is elevation of mandible, its superficial layer may also aid in protruding the mandible. When the mandible is protruded and biting force is applied, the fibers of the deep portion stabilize the condyle against the articular eminence.

The Temporalis Muscle

- **Origin and insertion**—it is fan shaped and arises from whole of the temporal fossa and from the deep surface of temporal fascia. Its fibers converge and descend into tendon which passes through the gap between the zygomatic arch and the side of the skull to be attached to the medial surface, apex, anterior and posterior borders of the coronoid process and the anterior border of the ramus of mandible nearly as far as the last molar teeth (Fig. 3-5).
- **Nerve supply**—it is supplied by the two deep temporal branches of anterior trunk of the mandibular nerve.
- **Blood supply**—it is supplied by middle and deep temporal arteries. The middle temporal artery is a branch of the superficial temporal artery. The deep temporal artery is a branch of internal maxillary artery.
- **Function**
 - When the entire temporalis contract, it elevates the mandible.
 - Its middle fibers have a retracting component because of their oblique direction downward and forward.
 - Its posterior fibers retract the protruded mandible.

Fig. 3-5: Origin and insertion of temporalis muscle.

Lateral Pterygoid

- **Origin and insertion**—It is a short thick muscle with two heads. Upper arises from the infratemporal surface and infratemporal crest of the greater wing of sphenoid bone and lower from the lateral surface of lateral pterygoid plate. Its fibers pass backward and laterally to be inserted into the pterygoid fovea on the anterior surface of the neck of the mandible and into the articular capsule and disc of temporomandibular joint (Fig. 3-6).

- **Nerve supply**—it is supplied by a branch of the anterior trunk of mandibular nerve.
- **Blood supply**—branch of maxillary artery.
- **Function**
 - It assists in opening the mouth by pulling forward the condylar process of the mandible and the articular disc, while the head of the mandible rotates on the articular disc.
 - During closure of mouth, backward gliding of the articular disc and condyle of the mandible are controlled by slow elongation of lateral pterygoid with medial pterygoid of the same side.
 - The medial and lateral pterygoid muscle of both sides contract alternately to produce side-to-side movement of the mandible.
 - When medial and lateral pterygoid of both sides act together, they protrude the mandible.

Fig. 3-6: Origin and insertion of lateral pterygoid muscle.

Medial Pterygoid

- **Origin and insertion**—it is a thick quadrilateral muscle attached to the medial surface of lateral pterygoid plate and the grooved surface of the pyramidal process of the palatine bone above. It has a superficial head which originates from the tuberosity of the maxilla and adjoining bone. Its deep head originates from the medial surface of medial pterygoid plate and the lateral surfaces of pyramidal process of palatine bone. Its fibers pass downward, laterally and backward and are attached by strong tendinous lamina to the posterior inferior part of the medial surfaces of the ramus and the angle of mandible as high as mandibular foramen and as forward as mylohyoid groove (Fig. 3-7).
- **Nerve supply**—it is supplied by branch of the mandibular nerve.
- **Blood supply**—it is supplied by the branch of maxillary artery.
- **Functions**—it helps in the elevation of mandible. Acting with the lateral pterygoid, they protrude the mandible.

Fig. 3-7: Origin and insertion of medial pterygoid muscle.

Bones

The skull consists of the 22 bones. Out of which, 8 are paired and 6 are unpaired. Paired bones are parietal, temporal, maxilla, zygomatic, nasal, lacrimal, palatine and inferior nasal concha. Unpaired bones are frontal, occipital, sphenoid, ethmoid, mandible and vomer. From dental point of view, maxilla and mandible are the most important and they are described below:

Maxilla

The maxilla consists of a central body, which is hollowed out forming the maxillary sinus and four processes (Fig. 3-8).

- **Frontal process**—it ascends from the anteromedial corner of the body, serves as the connection with the frontal bone.
- **Zygomatic process**—it forms in the lateral corner of the body, connects with the zygomatic bone.
- **Palatine process**—it is horizontal and arises from the lower edge of the medial surface of the body.
- **Alveolar process**—it extends downwards and carries the socket for the maxillary teeth.

Fig. 3-8: Maxilla showing frontal process (red arrow) zygomatic process (green arrow) and alveolar process (yellow arrow).

- *Body of maxilla*—the body of maxilla is three side pyramid with its base facing the nasal cavity (**Fig. 3-9**). It lies in an almost horizontal axis with its apex being elongated into the zygomatic process.

Fig. 3-9: Front view of maxilla.

- *Side of maxilla*—the three sides are superior or orbital (it forms greater part of the orbital floor), an anterolateral or malar (surface forming part of the skeleton of the cheek and face) and posterolateral or infra-temporal (surface turned towards the infra-temporal fossa).
- *Base*—the base is rimmed on its inferior edge by the alveolar process housing the teeth row.
- *Alveolar process*—alveolar process consists of two roughly parallel plates of bone that unite behind the last tooth to form a small rough prominence, the alveolar

Fig. 3-10: Palatal view of maxilla showing incisive foramen (red arrow).

tubercle, which often contains a single large marrow process. The lateral and external alveolar plate continues upward into the anterolateral and posterolateral surface of the maxillary body. The internal alveolar plate continues into the palatine process and behind the posterior end of the latter into the nasal surface of the maxillary body. The deep furrow between the two alveolar plates is divided by radial bony plates into the sockets of the individual teeth.

- *Incisive foramina*—at the boundary between two portions of the nasal crest, a canal commences in the nasal floor close to the midline and extends downwards, anteriorly and medially to unite with the canal of the other side in a common opening which is called as *incisive or nasopalatine canal* (**Fig. 3-10**). On the anterior surface of maxilla, there is canine fossa situated lateral to the canine eminence.

Mandible

It is the largest and strongest bone of the face. It consists of a horseshoe shaped body continuous upward and backward on either side with the mandibular rami.

- *Body*—the body is thick, has a rounded lower border and carries the alveolar process on its upper border. It extends backward from the chin at the midline symphysis to the anterior limit of the ramus.
- *Ramus*—it is a thick quadrilateral plate which extends backward from the groove for the facial artery (antegonial notch) to include the region called the mandibular angle (**Fig. 3-11**). The anterior border of the ramus continues along the body lateral to the alveolar process as a blunt ridge, the oblique line, running downward and forward to disappear at about the level of the 1st molar.

Fig. 3-11: Overview of mandible showing body and ramus of mandible.

- *Mental protuberance*—in the midline of anterior surface of the body projects a triangular prominence called mental protuberance.
- *Symphysis menti*—it is the line at which the right and left halves of the bone meet each other.
- *The mental foramen*, through which the mental nerve and blood vessels pass, is located on the lateral surface of body between the roots of the 1st and 2nd premolars. In the vertical dimension, the foramen lies halfway between the lower border of mandible and the alveolar margin.
- *Genial tubercle*—slightly above the lower border on its inner surface the mandibular symphysis is elevated in more or less sharply defined projection called as genial tubercle.
- *Mylohyoid line*—it is a prominent ridge that runs obliquely downward and forward from below 3rd molar tooth to the medial area below the genial tubercle. Below the mylohyoid line, the surface is slightly hollowed out to form submandibular fossa, which lodges the submandibular gland.
- *Mandibular canal*—the mandibular canal which houses the inferior alveolar nerve and blood vessels begins at the mandibular foramen, curves downward and forward and turns into a horizontal course below the roots of the molars. In the region of the premolars, the mandibular canal splits into two canals of unequal width; the narrower incisive canal continues the course of mandibular canal toward the midline and the wider branch, the mental, turns laterally, superiorly and posteriorly to open at the mental foramen (Fig. 3-12).

Fig. 3-12: Side view of mandible showing mental foramina (red arrow).

- *Alveolar bone*—the alveolar plates consist of two compact bony plates, the external and internal alveolar plate. These two plates are joined to each other by radial interdental and in the molar region, by inter-radicular septa, thus forming the sockets for the teeth in the same manner as in the upper jaw.

- *Digastric fossa*—the lower border of the mandible is also called as base. Near the midline, the base shows an oval depression called *digastric fossa*.

Trigeminal Nerve

The trigeminal nerve is the 5th cranial nerve and is also the largest. It has a large sensory root and a small motor root. It is attached to lateral part of pons by its two roots. It conveys both exteroceptive and proprioceptive impulses. Exteroceptive impulses of touch, pain and thermal senses are transmitted from skin of face, forehead, mucous membrane of nasal and oral cavity, sinus, and floor of mouth, teeth and anterior 2/3rd of tongue. Proprioceptive impulses of deep pressure are conveyed from teeth, periodontium, hard palate and temporomandibular joint receptors.

Branches of Trigeminal Nerve (Fig. 3-13)

Ophthalmic division

It is the smallest branch of semilunar ganglion and passes forward in the lateral wall of cavernous sinus.

- *Lacrimonal nerve*—it supplies sensory fibers to the gland and the adjacent conjunctiva.
- *Frontal nerve*—it divides into *supraorbital nerve* (supplies the skin of the upper eyelid, forehead and the anterior scalp region to the vertex of skull), and *supratrochlear nerve* (supplies skin of the upper eyelid and lower medial portion of forehead).
- *Nasociliary nerve*—it gives numerous branches. It includes branches in orbit (*Long ciliary nerves, posterior ethmoid nerve, anterior ethmoid nerve, external nasal branches*), branches arising in nasal cavity and terminal branches on the face.

Fig. 3-13: Different branches of trigeminal nerve supplying to face.

Maxillary division

It is intermediate division, and entirely sensory. It enters the orbit through inferior orbital fissure. It is now named *infraorbital nerve* and having traversed the infraorbital groove and canal in floor of orbit, it appears on face through infraorbital foramen. Branches are divided into 4 groups

- *Middle meningeal nerve*—supplies the dura with sensory fibers.
- *Ganglionic branches*—they contain secretomotor fibers for the lacrimal gland and sensory fibers for orbital periosteum and mucous membranes of the nose, palate and pharynx.
- *Zygomatic nerve*—it is divided into two branches, i.e. *zygomaticofacial* (supplies sensory fiber to skin over the prominence of zygomatic bone) and *zygomaticotemporal* (it supplies sensory fibers to skin over anterior temporal fossa region).
- *Posterior superior alveolar nerve*—it gives sensory branches to mucous membrane of sinus. It also supplies the maxillary molars and their gingivae.
- *Middle superior alveolar nerve*—it supplies upper premolar and mesiobuccal root of upper first molar.
- *Anterior superior alveolar nerve*—it supplies roots of maxillary central and lateral incisors. They also send branches to superior dental plexus of nerves within maxilla. They also supply mucous membrane of anterior part of maxillary sinus as well as labial gingivae of incisors and cuspid teeth.
- *Inferior palpebral branches*—they supply sensory fibers to skin of lower eyelid and its conjunctiva.
- *External or lateral nasal branches*—they supply skin of side of nose.

- *Superior labial branches* - three or more in number and supply skin and mucous membrane of upper lip and labial glands.

Mandibular Nerve

It is the largest of the three divisions. It is divided into following branches:

- *Nervus spinosus*—it supplies dura and mastoid cells.
- *Nerve to internal pterygoid muscle*—it supplies internal pterygoid muscle.
- *Pterygoid nerve*—it enters medial side of external pterygoid muscle to provide motor nerve supply.
- *Masseter nerve*—it supplies masseter muscle.
- *Anterior deep temporal nerve*—it ends in deep part of anterior portion of temporal muscle.
- *Posterior deep temporal nerve*—it passes upward to deep part of temporal muscle.
- *Long buccal nerve*—it supplies mandibular 2nd and 3rd molars. It then sends fibers to mucous membrane and skin of cheek, retromolar triangle, and buccal gingivae of mandibular molars and mucous membrane of lower part of buccal vestibule.
- *Auriculotemporal nerve*—it traverses upper deep part of parotid gland and then crosses the posterior root of zygomatic arch. It passes with superficial temporal artery in its upward course and then divides with numerous branches to tragus of external ear, to scalp, to the ear and as far upward as vertex of skull.
- *Parotid branches*—they are sensory, secretory and vasomotor fibers to the gland.
- *Articular branches*—it enter the posterior part of the temporomandibular joint.

TABLE 3-1: Lymphatic drainage of head and neck

<i>Nodes</i>	<i>Sites</i>
Occipital	Scalp, posterior to the ear and occipital region
Posterior auricular	External ear, scalp above and behind the ear.
Anterior auricular (pre-auricular/parotid)	Skin anterior to the temple, external meatus, lateral forehead, lateral eyelids, infraorbital nodes, posterior cheek, part of the outer ear, parotid gland
Inferior auricular (infra-auricular)	Pre- and post-auricular nodes
Infra-orbital	Skin of inner corner of the eye, skin of anterior face, and superficial aspect of the nose
Buccal	Skin over the anterior face, mucous membrane of the lips and cheeks, occasionally mandibular and maxillary teeth and gingivae
Submental	Tip of the tongue, midportion of the lower lips, chin, lower incisors and gingivae
Mandibular (supra-mandibular)	Skin over the mandible, mucous membrane of the lips and cheeks. Occasionally, maxillary and mandibular teeth and gingivae.
Submandibular (sub-maxillary)	Upper and lower teeth and gingivae except mandibular incisor, anterior nasal cavity, palate, body of tongue, upper lip, lateral angle of eye, submental nodes
Superficial cervical	Pinna and adjacent skin, pre- and post-auricular nodes
Deep cervical	Submandibular, submental, inferior auricular, tonsillar and tongue nodes

Fig. 3-14: Lymphatic drainage of face.

- *Auricular branches*—it supplies the skin of helix and tragus.
- *Meatal branches*—two small branches which supply skin lining the meatus and tympanic membrane.
- *Terminal branches*—they supply scalp and temporal region.
- *Lingual nerve*—It gives off small branches that are sensory to part of tonsil and mucous membrane of posterior part of oral cavity. It is sensory to mucous membrane of oral cavity, anterior 2/3rd of tongue (along with chorda tympani nerve), floor of mouth and gingivae on lingual surface of the mandible.
- *Inferior alveolar nerve*—it is the largest branch of posterior division of mandibular nerve. It sends motor branches to mylohyoid muscle and anterior belly of digastric muscle. It then enters mandibular foramen and descends in the mandible in the inferior dental canal as inferior alveolar nerve. It is sensory to mandibular teeth, body of mandible and labial gingiva anterior to bicuspid teeth.
- *Mental nerve*—it passes through mental foramen on lateral surface of mandible. It is sensory to skin of chin, lower lip, and mucous membrane lining of lower lip.
- *Incisive nerve*—it continues anteriorly in the inferior dental canal to midline. It is sensory to anterior teeth and labial gingivae.

Lymphatic Drainage of Head and Neck

It is described in **Table 3-1** and **Fig. 3-14**.

Immunity, Antigen-Antibody Reaction

Immunity

The word immunology derived from Latin word 'immunis' meaning 'free of burden'. "It is the resistance exhibited by the host towards injury caused by microorganisms and their products". It is a reaction of body against any foreign antigens. Immunity against infectious diseases consists of two main types, each with humoral and cellular components and their effective cells. The importance of immune system occurs in life-threatening infection suffer by patient with immune defect.

Uses of Immunity

- *Understanding the disease*—it helps to understand the etiology and pathogenesis of many diseases.
- *Vaccine*—development of vaccine can be done with the help of immunity.
- *Treatment*—treatment of many diseases can be done with antibodies.
- *Future susceptibility*—it helps to find with future susceptibility to disease with the help of HLA typing system.

Classification (Fig. 4-1)

- **Innate immunity**
 - Non-specific
 - Specific
- **Acquired**
 - Active
 - Natural
 - Artificial
 - Passive
 - Natural
 - Artificial
- **Local**
- **Herd**

Fig. 4-1: Different types of immunity—
A diagrammatic representation.

Innate Immunity

This is also called as natural immunity. This comprises of preexisting non-specific defences. It is the resistance to infection, which an individual possesses by virtue of his genetic and constitutional make up. It does not depend upon the prior contact with microorganisms or immunization. Innate immunity can be considered at the level of race, species or at individual's levels.

Types of Innate Immunity

- *Specific and non-specific*—it may be *non-specific* when it indicates degree of resistance to infection in general or *specific* when resistance to particular pathogen is concerned.
- *Species immunity*—it refers to total or relative refractoriness to a pathogen shown by all members of a species e.g. all human beings are totally unsusceptible to plant pathogens and to many pathogens of animals, such as rinderpest or distemper. It may be due to physiological and biochemical differences between the tissues of different host species, which determine whether a pathogen can multiply or not.
- *Racial immunity*—within species, different races may show differences in susceptibility to infection. This is called as 'racial immunity' e.g. high resistance of Algerian sheep to anthrax. Such racial differences are known to be genetic in origin.
- *Individual immunity*—the differences in individual immunity exhibited by different individuals in a race is called as 'individual immunity' e.g. homozygous twins exhibit similar degree of resistance or susceptibility to lepromatous leprosy and tuberculosis. Such correlation is not seen in heterozygous twins.

Factors Affecting Innate Immunity

- *Age*—the two extremes of life carry higher susceptibility to infection as compared to adults. The fetus *in utero* however is protected from maternal infection by the placental barrier.
- *Hormonal influence*—endocrine disorders such as diabetes mellitus, hypothyroidism and adrenal dysfunction are associated with an enhanced susceptibility to infection. Corticosteroids exert an important influence on response to infection. The elevated steroid levels during pregnancy may have a relation to heightened susceptibility of pregnant women to many infections.
- *Nutrition*—in general, both humoral and cell mediated responses are reduced in malnutrition. Cell mediated immune response such as *Mantoux* test becomes negative in severe protein deficiency. Certain infections may not become clinically apparent in severely malnourished patients.

Mechanism of Innate Immunity

- *Epithelial surface*—skin and mucous membrane covering the body gives protection against bacteria. They act as mechanical barrier.
- *Humoral factors*—it consists of lysozyme, properdin, betalysin, C-reactive protein, bactericidin etc.
- *Cellular factors*—it includes phagocytosis, and inflammation.

Acquired Immunity

The resistance that an individual acquires during life is known as '*acquired immunity*'. It is of two types.

Active Immunity

It is resistance developed by an individual because of antigenic stimulus. This involves active functioning of host's immune apparatus leading to synthesis of antibodies or production of immunologically active cells. Once the active immunity develops, it is long lasting. It is also of two types.

- *Natural*—it results from either a clinical or an inapparent infection with the parasite, e.g. a person who has recovered from an attack of smallpox develops natural immunity to it. The immunity following bacterial infection is generally less permanent than that following a viral infection.
- *Artificial*—it is the resistance induced by vaccines, which are preparations of live or killed microorganisms or their product.

Passive Immunity

The resistance that is transmitted to a person in readymade fashion is known as passive immunity. There is no antigenic stimulant, instead preformed antibodies are administered. There is no latent period, protection being effective immediately after passive immunization. It is less effective and inferior to active immunization, but it is immediate in action and can be employed when instant immunity is needed. It is also of two types.

- *Natural*—it is the resistance passively transferred from mother to baby. By active immunization of mothers during pregnancy, it is possible to improve the quality of passive immunity in the infants.
- *Artificial*—it is passively transferred to the recipient by the administration of antibodies. The agent used is hyperimmune sera of animal or human origin, convalescent sera and pooled human gamma globulin.

Local Immunity

It is important in treatment of infection, which is either localized or due to surgeries (postoperative infection), in combating infections at the site of primary entry of the pathogen. Natural infection or the live virus vaccine administered provides local immunity.

Herd Immunity

This refers to the overall level of immunity in a community and is relevant in the control of epidemic diseases. When a large proportion of individuals in a community (herd)

is immune to a pathogen, herd immunity to a pathogen is satisfactory. When herd immunity is low, epidemics are likely to occur on the introduction of a suitable pathogen.

Antigen-Antibody Reaction

Antigen

- **Definition**—any substance which when introduced parenterally into a body stimulates the production of an antibody, with which it reacts specifically and in an observable manner. The immune system can respond to antigen either by cell mediated immunity or by humoral immunity.
- **Size**—most antigens are large molecules (over 1000 molecular weight). Smaller molecules do not provoke an immune response unless bound to large carrier molecules. The complete antigen is able to induce antibody formation and produces a specific and observable reaction with the antibody so produced.
- **Haptens**—these are substances which are incapable of inducing antibody formation by themselves, but can react specifically with antibodies.
- **Epitope**—the smallest unit to antigenicity is known as an *epitope* or antigenic determinant.

Antibody

Antibody is produced by plasma cells in the lymph nodes, bone marrow and spleen. The cells are ovoid with an eccentrically placed nucleus. The cytoplasm is basophilic. One plasma cell produces antibody of one class, reactive with only one antigen. There are five classes of immunoglobulins which are as follows:

IgG

It is the most abundant immunoglobulin in the plasma and extracellular fluid. It can cross placenta and is important in passive transfer of immunity to the fetus. It is capable of neutralizing toxins and may be cytolytic through the activation of a complement. Polymorphs and macrophages have surface receptors for Fc fragment of IgG, thus binding of IgG to particular antigens promotes adhesion of these cells and subsequent phagocytosis of antigen.

IgA

It is secreted locally by plasma cells in the respiratory passages, salivary and lacrimal glands and intestinal mucosa. It is an important constituent of breast milk. IgA occurs in two forms, serum IgA is principally a monomeric

7S molecule found on mucosal surfaces and in secretions. It is a dimer formed by two monomer units joined together at their carboxyterminals by glycopeptides termed the 'J chain'. This is called as secretory IgA. It can activate complement by the alternative pathway.

IgM

It is formed by J chains into pentamers of the Ig molecules and these attain very high molecular weight of 9000,000. The large molecular size prevents it from leaving the plasma, except when permitted by increased vascular permeability in inflammatory lesions. As it has antigen combining sites, it has good agglutinating and complement fixing properties. It is the first class of antibodies to be formed in immune response.

IgE

It binds selectively to mast cells and to basophils by its Fc fragment. The binding of antigen to its Fab fragment triggers reflex of histamine and other substances which are important in anaphylactic type of hypersensitivity.

IgD

The function of IgD is largely unknown, but it may act as an antigen receptor on the lymphocyte surface.

Antigen–Antibody Reaction Mechanism

Antigen-antibody reaction *in vitro* is known as *serological reaction* (Fig. 4-2).

Fig. 4-2: Diagrammatic representation of antigen-antibody reaction.

- **Primary state**—In this, there is initial interaction between the two without any visible effect. This reaction is rapid and occurs even at low temperature and also is reversible because inter-molecular forces between Ag and Ab are weaker.
- **Secondary state**—it leads to precipitation, agglutination, lysis of cells, killing of live antigens, neutralization of motile organisms and enhancement of phagocytosis. An antigen can stimulate production of different types of immunoglobulins, which differ in their reaction capability and other properties.
- **Tertiary state**—some antigen-antibody reactions occurring *in vivo* initiate chain reactions that leads to neutralization or destruction of injurious antigens or tissue damage. These are tertiary reactions and include humoral immunity against infectious diseases, clinical allergy and other immunological diseases.

General Features of an Antigen-Antibody Reaction

- **Specific**—the reaction is specific; an antigen combines only with its homologous antibody and vice versa. Entire molecule reacts and not its fragments.
- **Non-degenerative**—there is no degeneration of the antigen or antibody during the reaction.
- **Combination**—the combination occurs at the surface, which is firm and reversible. Antigen and antibody can combine in varying proportions.

Precipitation Reaction

- **Formation of insoluble precipitate**—when a soluble antigen combines with antibody in the presence of electrolyte (NaCl) at a suitable temperature and pH, the antigen-antibody complex forms an insoluble precipitate which is greatly influenced by the relative proportions of antigens or antibodies.
- **Results**—if into the same amount of antiserum in different tubes, increasing quantities of antigens are added, precipitation will be found to occur most rapidly and abundantly in one of the middle tubes in which Ag and Ab are present in optimal or equivalent proportion. The precipitation will be weak in proceeding or later tubes (Fig. 4-3).

Agglutination Reaction

- **Mechanism**—when the particulate antigen is mixed with its antibody in the presence of the electrolyte at a suitable temperature and pH, the particles are clumped or agglutinated. It is more sensitive than precipitation for the detection of an antibody. It occurs optimally

Fig. 4-3: Precipitation reaction—A diagrammatic representation.

Fig. 4-4: Agglutination reaction.

when an antigen and antibody react in equivalent proportions. Better agglutination reaction takes place with IgM antibody than with IgG antibody (Fig. 4-4).

Complement Fixation Test

- **Mechanism**—complement takes part in many immunological reactions and is absorbed during the combination of antigens with their antibodies. The ability of antigen-antibody complexes to fix complement is made to use in the complement fixation test. This is a very sensitive and a versatile test.

- **Component**—it consists of five reagents which are antigen, antibody, complement, sheep erythrocytes, and amboceptor. Each of these has to be separately standardized.
- One unit or minimum hemolytic dose of complement is defined as the highest dilution of guinea pig serum that lyses one unit volume of washed sheep erythrocyte in the presence of excess of hemolysin (amboceptor) within a fixed time (usually 30 or 60 minutes) and at a fixed temperature (37°C) (Figs 4-5 and 4-6).

Fig. 4-5: Positive complement fixation test.

Fig. 4-6: Negative complement fixation test.

Virus Neutralization Test

Neutralization of viruses by their antibodies can be demonstrated in various systems. Neutralization of bacteriophages can be demonstrated by the plaque inhibition test. Neutralization of animal viruses can be seen in three systems: animal, eggs and tissue culture.

Immunofluorescence

- *Mechanism*—fluorescence is a property of absorbing light rays of one particular wavelength and emitting rays with different wavelengths. Fluorescence dye can be conjugated to antibodies and such labelled antibodies can be used to locate and identify antigen in tissue.

- *Use*—this test can be used for identification of bacteria, viruses or other antigens using specific antisera labelled with fluorescence dyes.
- *Dye use*—commonly used dye is fluorescein isothiocyanate and lissamine rhodamine exhibiting blue-green and orange-red fluorescence respectively.

Neoplasm

Definition

It is an abnormal mass of tissue, growth of which exceeds and is uncoordinated with that of normal tissues and persists in the same excessive manner, after cessation of the stimuli that evokes the changes.

Oncology is the study of neoplasm.

Nomenclature

There are mainly of two types neoplasm: benign and malignant. Benign tumors are designated by attaching '*oma*' to cell of the organ. Malignant tumors arising from mesenchymal tissues are known as '*sarcomas*', like osteosarcoma. Malignant tumors of epithelial origin are called '*carcinoma*', like adenocarcinoma and squamous cell carcinoma.

Normal Cell Cycle

All renewing cells go through a series of events known as cell cycle. Successive phases of progression of cell cycle are described below (Fig. 5-1).

- *G₁ phase*—after mitosis (M phase), cells spend a variable period of resting (*G₁ phase*) where DNA synthesis is absent but the synthesis of RNA and protein continues.
- *S phase*—at the end of *G₁ phase*, unknown signals continuously institute a burst of RNA synthesis which is followed by DNA synthesis (*S phase*). Then the cells undergo replication or remain polyploid and eventually die.
- *G₂ phase*—the cells cease DNA synthesis during *G₂ phase* and DNA content is fairly constant in the growing normal cells. The proportion of cells population undergoes active proliferation in the cycle is termed as growth fraction.

Fig. 5-1: Normal cell cycle—A diagrammatic representation.

- *G₀ phase*—daughter cells may continue to remain in cell cycle and divide further or may go out at the cell cycle in resting phase.

Predisposing Epidemiologic Factor for Development of Neoplasm

Hereditary Predisposition

The risk of developing cancer in relatives of a known cancer patient is three times higher than control study. Genetic cancers comprise not greater than 5% of all cancers, e.g. retinoblastoma, familial polyposis coli, cancer of breast etc.

Racial and Geographic Factors

Cancers are largely due to the influence of environment and geographic differences affecting whole population such as climate, water, diet, habit. For example—

- Black Africans commonly have cancers of skin, penis, cervix, and liver. Europeans and Americans commonly develop malignancies of lung, breast, and colon.

- Carcinoma of stomach is five times higher in Japanese than in Americans.
- Nasopharyngeal cancer is common in south East Asians.

Environmental and Cultural Factors

We are surrounded by an environment of carcinogens which we eat, drink, inhale and touch (Fig. 5-2). For example—

- Cigarette smoking is the etiology of cancer of oral cavity, pharynx, larynx, esophagus, lung, pancreas and urinary bladder.
- Alcohol causes cancer of esophagus and liver.
- Alcohol and tobacco together accelerate the risk of developing cancer of upper aerodigestive tract.
- Betel nut chewing causes cancer of cheek and tongue.
- Industrial and environmental materials are carcinogenic. This includes exposure to substances like arsenic, asbestos, benzene, and naphthylamine.
- Overweight individuals, deficiency of vitamin A, people consuming foods rich in animal fats and low in fiber content have more risk of developing cancers like colonic cancer.

Age

Generally, it occurs in older individuals past 5th decade of life but, there is variation in age groups. For example, acute leukemia occurs in children, neuroblastoma in infancy.

Fig. 5-2: Different types of etiological factors responsible for formation of neoplasm.

Sex

It is generally more common in men except cancer of breast, gallbladder, and thyroid.

Acquired Preneoplastic Conditions

These may be inflammatory, hyperplastic conditions or may be certain benign tumors. It includes chronic atrophic glossitis, leukoplakia of oral cavity, vulva and penis, cirrhosis of liver, chronic irritation and multiple neurofibromas.

Carcinogenesis

Carcinogenesis or oncogenesis or tumorigenesis means induction of tumors; agents which can induce tumors are called carcinogens. Carcinogens are broadly divided into four groups (Fig. 5-3):

- Chemical carcinogens
- Physical carcinogens (radiation)
- Hormonal carcinogens
- Biologic carcinogens (virus)

Fig. 5-3: Types of carcinogenesis.

Chemical Carcinogenesis

Chemical carcinogens are divided into two broad groups:

Initiators of Carcinogenesis

- *Direct-acting carcinogens*—these require no metabolic conversion to become carcinogens.
- *Alkylating agents*—it includes, various chemotherapeutic drugs that have successfully cured, controlled or delayed recurrence of certain types of cancers only to later evoke a second form of cancer usually leukemia. Various agents used are cyclophosphamide, chlorambucil, busulfan, melphalan, nitrosourea, β -propiolactone and epoxides. This tragic consequence is called as “*Pyrrhic victory*” which becomes less of a victory when their initial use has been converted to cause later on second form of cancer.
- *Acylating agents*—substances like acetyl imidazole.
- *Indirect-acting carcinogens or procarcinogens*—these are chemical substances requiring metabolic activation for becoming potent initial carcinogens.
- *Polycyclic aromatic hydrocarbons* (in tobacco, smoke, animal foods, industrial oil, and atmospheric pollutants). Important chemical compounds included are benzanthracene, benzapyrene, methylcholanthrene. They may cause lung cancer, skin cancer, cancer of oral cavity, and sarcoma.
- *Aromatic amines and azo dyes*—These are β -naphthylamine, benzidine, azo dyes used for coloring foods, and acetyl aminofluorene. They may cause bladder cancer and hepatocellular carcinoma.
- *Naturally occurring product*—Aflatoxin, actinomycin-D, mitomycin-C, safrole, and betel nut. It can cause hepatocellular carcinoma.
- *Miscellaneous*—nitroso compounds, vinyl chloride monomer, asbestos, arsenical compounds, metals like nickel, lead, chromium, and insecticides, fungicides can cause gastric carcinoma, hemangiosarcoma of liver, bronchogenic carcinoma, epidermal hyperplasia, basal cell carcinoma, and lung cancer.

Promoters of Carcinogenesis

Certain chemical substances lacking the intrinsic carcinogenic potential but helping the initiated cell to proliferate further are called promoter of carcinogenesis. E.g. phorbol, phenols, drugs like phenobarbital, and artificial sweetener like saccharine.

Mechanism of Action

- *Binding to DNA and RNA*—the great majority of chemical carcinogens are mutagens. They bind directly to DNA and RNA or cytoplasmic proteins to specific sites within

molecule inducing miscoding error during transcription and replication.

- *Factors affecting a carcinogenicity*
 - *Dose dependent*—the carcinogenicity of chemical agents is dose dependent and multiple traditional doses have same oncogenicity as a single comparative dose.
 - *Administration of promoters*—the carcinogenicity of chemical agents can be significantly enhanced by the subsequent administration of promoters. To be effective, the promoter must follow the initiator.

Stage of Chemical Carcinogen

The phenomenon of cellular transformation by chemical carcinogenesis is a progressive process involving two different stages. These are initiation and promotion.

Initiation

In this initiator carcinogen interact with DNA of target cell to induce mutation that is more or less irreversible to transform it into initiated cell.

- *Metabolic activation*—only indirect acting carcinogen or procarcinogens require metabolic activation chiefly by mixed oxidases of cytochrome P-450 system located in microsomal compounds of the endoplasmic reticulum or in the nucleus.
- *Reactive electrophiles*—they are electron deficient protons, which bind to electron rich portions of other molecules of cell such as DNA, RNA or other protein.
- *Target molecules*—the primary target is DNA, producing mutagenesis.
- *Initiated cell*—the unrepaired damage produced in the DNA of the cell becomes permanent, only if the altered cell undergoes at least one cycle of proliferation.

Promotion

It does not damage the DNA but enhances the effect of direct-acting carcinogen or procarcinogens. The ultimate effect is further clonal proliferation of the initiated cell. Two or more initiators may be chemical, oncogenic virus or radiant energy may act in concert to induce malignant transformation referred to as cocarcinogens.

Physical Carcinogenesis

It is divided into two groups.

Radiation Carcinogenesis

- *Forms of radiation*—radiation whenever in the form of UV light from sunlight, UV lamp, welder's arc, or ionizing radiation like X-ray, α , β and γ ray, radioactive isotopes, protons and neutrons are established carcinogens.
- *Example of radiation induced cancers*—most frequent radiation induced cancers are leukemia, cancer of

thyroid, skin, breast, lung, and salivary gland. Therapeutic irradiation can also induce carcinogenesis.

- *Facts about radiation causing cancer*—radiant energy have potential of producing mutation and even killing cells. It can affect carcinogenesis by the following facts:
 - Few tumors appear only after long latent period during which successive generation of clones are developed.
 - The radiation initiation is generally irreversible, but at a low dosage level is amenable to repair.
 - The effect of radiation depends upon a number of factors such as type of radiation, dose, length of interval between the doses, capability of cells to repair in intervals and various host factors such as age, individual susceptibility, immune competence, hormonal influence and type of cell irradiated.
- *Mechanism*—it induces cancer by following mechanism;
 - Radiation may directly alter the cellular DNA and it may dislodge ions from water and other molecules of cell and result in the formation of highly reactive free radicals that may bring about the damage.
 - Radiation mutation may render cell vulnerable to other carcinogenic influence, i.e. acting as co-carcinogen.
 - Inhibition of cell division and inactivation of enzymes.
 - Radiation might cause cell killing; permitting survivors to proliferate and thereby, become vulnerable to oncogenic influence.

Non-radiation Physical Carcinogenesis

Mechanical injury to tissues such as from stones in the gall bladder, stones in the urinary tract, and healed scars following burns or trauma has been suggested as causes of increased risk of carcinoma.

Implants of inert materials such as plastic, glass, etc. in prosthesis and foreign bodies like metal foils observe to cause tumor development in experimental animals.

Hormonal Carcinogenesis

Carcinoma is most likely to develop in organs and tissues which undergo proliferation under influence of excessive hormonal stimulation. Hormone sensitive tissues developing tumors are breast, endometrium, myometrium, vagina, thyroid, liver, prostate, and testis.

- *Estrogen*—in experimental animals, estrogen can cause induction of breast cancer in mice. Other cancers which can be induced in mice by estrogens are squamous cell carcinoma of cervix, connective tissue tumor of myometrium, tumor of kidney in hamsters, and benign and malignant tumors of liver in rats. In case of human women receiving estrogen therapy and women with estrogen secreting granulosa cell, tumor of the ovary have

increased risk of developing endometrial carcinoma. Adenocarcinoma of the vagina is seen with increased frequency in adolescent daughter of mother who had received estrogen therapy during pregnancy.

- *Contraceptive hormones*—there is increased risk of developing breast cancer, benign tumors of the liver and few patients have developed hepatocellular carcinoma.
- *Anabolic steroids*—consumption of anabolic steroids by athletes to increase the muscle mass also increases the risk of developing benign and malignant tumor of the liver.
- *Hormone dependent tumors*—it has been shown in experimental animals that induction of hyperfunction of adeno-hypophysis is associated with increased risk of developing neoplasia of the target organs following preceding functional hyperplasia.

Biologic Carcinogenesis

The epidemiological studies on different types of cancer indicate the involvement of transmissible biologic agents in their development, chiefly viruses. It has been estimated that about 20% of all cancers worldwide are virus associated cancers. Therefore biological carcinogenesis is largely viral oncogenesis. A large number of viruses have been proved to be oncogenic in wide variety of animals and in certain types of cancers in humans.

The association of oncogenic virus with neoplasia was observed by an Italian physician Sanarelli in 1889 who noted association between myxomatosis of rabbit with poxvirus. Oncogenic viruses fall into 2 broad groups, i.e. those containing ribonucleic acid are termed as RNA oncogenic viruses and those containing deoxyribonucleic acid are termed as DNA oncogenic viruses.

RNA Oncogenic Viruses

These are retroviruses, i.e. they contain the enzyme reverse transcriptase, which is required for reverse transcription of viral RNA to synthesize viral DNA strands. Based on their activity to transplant target cells into neoplastic cells, they all are divided into three subgroups:

- *Acute transforming viruses*—it includes Rous sarcoma virus in chickens, leukemia-sarcoma viruses of avian, feline, bovine and primate.
- *Slow transforming tumor viruses*—mouse mammary tumor virus (MMTV) that causes breast cancer in daughter mice.
- *Human T-cell Lymphotropic viruses (HTLV)*—it can cause adult T-cell leukemia-lymphoma syndrome and AIDS.

DNA Oncogenic Viruses

They are divided into five groups

- *Papovavirus group*—human papilloma virus, polyoma virus, SV-40 (simian vacuolating) virus.

- *Herpes virus*—Epstein Barr virus, Human herpesvirus, cytomegalovirus, Lucke's frog virus, Marek's disease virus.
- *Adenoviruses*—it can cause upper respiratory infections and pharyngitis. In man, they are not known to be involved in tumors but in hamsters they may induce sarcomas.
- *Poxvirus*—in rabbits, it can cause myxomatosis and in humans, it can cause molluscum contagiosum and may induce squamous cell papilloma.
- *Hepadnaviruses*—hepatitis B virus is a member of this family and it can cause acute hepatitis and is responsible for carrier state which can result chronic hepatitis. In some cases, to progressing to hepatic cirrhosis and into hepatocellular carcinoma.

Mechanism of Biological Carcinogenesis

RNA viral oncogenesis:

Reverse transcriptase acts as a template to synthesize a single strand of matching viral DNA.

- Single strand of viral DNA is then copied by DNA dependent DNA synthetase to form another strand of complementary DNA resulting in double stranded viral DNA or provirus.
- The provirus is then integrated into the DNA of the host cell genome and may transform the cell into a neoplastic cell.
- Virus replication begins after integration of provirus into host cell genome. Integration results in transcription of proviral genes or progenes into messenger RNA which then forms components of the virus particle, i.e. virion core proteins from gag gene, enveloped glycoprotein from env gene and reverse transcriptase from pol gene.
- The three components of virus particles are then assembled at the plasma membrane of host cells and virus particles released by budding off from plasma membrane, thus completing the process of replication.

DNA viral oncogenesis:

- *Replication*—The virus may replicate in the host cell with consequent lysis of infected cell and release of virions.
- *Integration*—The viral DNA may integrate into the host cell DNA. This results in neoplastic transformation of the host cell.

Oxidative Mechanism of Carcinogenesis

Active oxygen species and other free radicals have long known to be mutagenic. Further, these agents have emerged as mediators of the other phenotypic and genotypic changes that lead to form mutation to neoplasia.

Free radicals production is ubiquitous in all respiring organism and is enhanced by many disease states, by

carcinogen exposure and under conditions of stress. Free radicals may therefore contribute widely to cancer development in humans.

Free radicals scavenging vitamins C and E have been shown to protect against cancer development in animal models.

Biology of Tumor Growth

The life cycle of malignant tumors can be divided into four phases.

Induction of Malignant Changes in the Target Cell (Transformation) (Fig. 5-4)

- *Effect on genes*—large number of carcinogen agents induce neoplastic transformation of cells *in vivo* and in experimental animals. All etiologic factors ultimately affect the function of two sets of genes, one is proto-oncogenes or oncogenes and another one is *anti-oncogenes* or cancer suppressor genes.
- *Binding with DNA*—the majority of carcinogens are mutagens which bind the DNA directly or indirectly by undergoing enzymatic activation, inducing miscoding errors during transcription and replication.
- *Production of growth factors*—oncogenes may code for growth promoting factors and as a result, the tumor cells produce large amount of growth factors to which, only they can respond.

Fig. 5-4: Biology of tumor growth (induction phase).

- **Encoding**—oncogenes may encode a defective receptor that send stimulating signals to the cells, even in the absence of growth factors.
- **Multiple mutations**—cancer is a genetic disease that results when multiple mutations accumulate in the DNA of a cell and specific chromosomal abnormalities predispose to cancer.

Growth of Transformed Cells (Kinetics of Tumor Cell Growth) (Fig. 5-5)

- **Doubling**—the monoclonal cancer cell (10 μm in diameter) has to undergo about 30 population doublings to produce 10^9 cells weighing approximately 1 gm, which is the smallest clinical detectable mass. To produce a tumor of 10^{12} cells, weighing 1 kg approximately, which is usually the maximum size compatible with life, the tumor cells have to undergo 10 further population doublings. So by the time the tumor is clinically detectable, it has already complete a major portion of its life cycle.
- **Factors affecting growth of cells**—in tumor cells, there is an imbalance between cell production and cell loss, therefore, the tumor grows progressively. The rate of tumor growth depends upon the growth fraction and the degree of imbalance between cell production and cell loss.

Fig. 5-5: Biology of tumor growth (kinetic of tumor cell growth).

Mechanism of Local Invasion and Distant Metastases

- **Routes of metastasis**—there are three routes through which metastases of tumor cells occur, i.e. local invasion, via blood vessels and via lymphatics.
- **Local invasion**—the local invasion takes the path of least resistance and the tumor cells invade the surrounding tissue spaces.

- **Lymphatics spread**—in case of oral malignancies, distant metastasis is mainly via lymphatics, either by lymphatic permeation or by lymphatic embolism.
- **Blood vessels**—rarely, it spreads through blood vessels and if this occurs, the tumor cells invade the lumen of blood vessels, the tumor emboli form, which are fragmented and the tumor cells are lodged into distant tissues.

Theories of Carcinogenesis

The Epigenetic Theory

According to this theory, the carcinogenic agents act on the activators or suppressors of genes and not on the genes themselves and result in the abnormal expression of genes.

Genetic Theory

- **Concept**—this is the most popular theory which suggests that cells become neoplastic because of alteration in the DNA. It is suggested that, the secret of cancer lies within the normal cells themselves in the form of proto-oncogenes (C-oncs). The mutated cells transmit their characters to the next progeny of cells. Inappropriate over expression of the gene or point mutation cause the cell to produce stimulating growth factors or in some way damages normal regulatory control. The qualitative and quantitative changes in the expression of genome may be brought about by carcinogenic influence, i.e. chemical, viruses, radiation or spontaneous random mutations.
- **Oncogenes**—Oncogenes are the transforming genes present in many tumor cells. Closely related genes are detected on normal animal and human cells and are called as 'proto-oncogenes' or 'cellular oncogenes', abbreviated as 'c-oncs'.
- **'Cellular oncogenes'** of the host cells can transcribe its copies in the viral genome of acute transforming oncogenic retroviruses called as viral oncogenes or '*v-oncs*'. An alternate mechanism is by anti-oncogenes in which, there is inactivation or deletion of genes that normally perform the function of suppressing cell proliferation, thus allowing them to proliferate.
- **Feedback deletion**—according to genetic regulatory mechanism theory, primary change in the cell consists of a modification of repressor molecule which controls the functions of the gene. The repressor molecules are either RNA or protein. The modification of repressor molecules removes their orderly inhibitory control, which is responsible for normal morphogenesis and differentiation, and unearths the cell genetic potentiality for unrestricted growth. This concept of loss of growth control is described as '*feedback deletion*'.

Virus Theory

At some stage, it participates in the development of cancer. The concept of mode of action of virus has taken many forms-

- *Act as parasite*—virus is present as a parasite in all tumor cells and it is transmitted from cell-to-cell and stimulates extreme hyperplasia without affecting the genome cell.
- *Act as biologic carcinogen*—it acts as a biologic carcinogen on some cellular constituents to release or activate neoplastic potentialities normally present in cells.
- *Auto synthesis*—carcinogens of all kinds ultimately act by creating some new auto-synthesizing cytoplasmic constituents, probably an auto-catalytic protein, which can excite the cell to unlimited growth.

Immune Surveillance Theory

It suggests that an immune-competent host mounts an attack on developing tumor cells so as to destroy them while an immune-incompetent host fails to do so. According to original immunological theory, normal cells contain specific 'self-marker' (identity proteins) which is recognized by the normal growth regulating mechanism.

These proteins serve as receptor for chemical carcinogens (hapten) and the resulting complex is self-replicating. The complex (complex antigen) triggers off an immune response and the antibody (free or cell bound) combines with the self-marker carcinogen complex and eliminates it.

The new race of cells produced is deleted with self-markers and goes unrecognized by growth regulatory mechanism. The high incidence of cancer in AIDS patients is in support of this theory.

Monoclonal Hypothesis

Currently, there is strong evidence on studies of human and experimental animals that most of the cancers arise from single clone of transformed cell.

The best documentation of monoclonal origin of cancer cells come from the study of G₆PD in women who are heterozygous for its two isoenzymes A and B. It is observed that all tumor cells in benign uterine tumor (leiomyoma) contain either A or B genotype of G₆PD—i.e. the tumor cells is derived from a single progenitor cell.

Multistep Theory

According to this theory, carcinogenesis is a multistep process which is substantiated *in vitro* by changes in experimental animals as well as *in vivo* by changes in human cancers.

In chemical carcinogenesis, there are two essential features, i.e. initiation and promotion. Many tumors arise from combination of activation or growth promoting

oncogenes and inactivation of growth suppressing anti-oncogenes. In some cancers, there is initial dysplastic change that may progress into carcinoma *in situ* and then into invasive carcinoma.

Metastasis

'Metastasis is defined as spread of tumor by invasion in such a way that discontinuous secondary tumor mass/masses are formed at the site of lodgment'. This metastasis is the transfer of the disease from one organ or part to another not directly connected with it.

If malignant cells did not metastasize, the surgical removal of primary neoplasm would completely cure the patient. Metastasis is fundamentally an embolic process. The invasiveness of malignant cells involves motility, which requires change in shape and adhesiveness and ability to degrade the matrix in order to penetrate it.

Thus, a definition of the behavior of the metastatic tumor cells is the tendency to cross the tissue compartment / boundary and intermix with other cell types. The metastatic process can be divided into several sequential steps although these steps are interconnected.

Factors which control metastasis are proteolysis, cell adhesion, tumor angiogenesis, cell mediated immunity and genetic factor.

Steps of Metastasis

- *Breaking of cells*—the breaking of loose neoplastic cells from the parent tumor.
- *Invasion*—invasion of the matrix (sarcoma), penetration of the basement membrane and invasion of connective tissue (carcinoma).
- *Entering the blood vessels*—it then entering the wall of blood and lymphatic vessels.
- *Survival*—survival of malignant cells in the bloodstream. Survival in the compatible tissue environment and induction of growth factor to stimulate new vessel formation to obtain nutrition.
- *Emergence of cells*—emergence of the malignant cells from the blood vessels in the form of the emboli and lodgment in other tissues.
- *Multiplication*—multiplication of neoplastic cells and growth to form secondary neoplasm at the new site.
- *Control mechanism*—each of these steps is probably controlled by different molecular mechanism and this may explain the differences in the behavior with reference to tumor metastasis. Neoplastic cells within a single tumor might differ in their ability to metastasize. A sub-population of cells preexists within the heterogeneous primary tumor. The relative size of this sub-population in the primary tumor may vary with time between the neoplasms.

Routes of Metastasis (Fig. 5-6)

- *Lymphatics*—particularly for carcinoma and lymphosarcoma. For example, mouth-to-neck nodes and breast-to-axillary nodes.
- *Bloodstream*—particularly veins from gut via portal circulation to liver, from systemic sites through right heart to lung, from left heart to any systemic sites.
- *Cavities*—along epithelium lined cavities, for example: respiratory tract, gut, urinogenital tract etc.
- *Others*—transcelomic spread, cerebrospinal fluid, tissue planes and through nerve sheath.

Pattern of Metastatic Spread

- *Mechanistic theory*—the capillary bed of the first organ which encounter viable neoplastic cells is the preferred site of metastasis.
- *Seed and soil hypothesis*—it suggests that availability of fertile environment (the soil) in which compatible tumor cells (the seed) can grow is important. Ewing suggested that varying pattern of metastasis is due to fact that different tumor cells thrive in certain biological sites (soils) but not in the other sites.
- *Cell interaction*—interaction between cell surface protein of malignant cells and organ specific protein, e.g. fibronectin receptor.

Grading and Staging of Tumors

Grading

The grading features are those indicative of proliferation and differentiation. It is defined as, 'macroscopic and microscopic degree of differentiation of tumor'. Grading depends mainly on two histologic features, the degree of anaplasia and the rate of growth. Different types of grading systems are as follows:

Broder's Classification System (Fig. 5-7)

- *Grade I* (well differentiated, i.e. less than 25% anaplastic cells)—it is characterized by the presence of relatively mature cell with few nuclear aberration and with the presence of keratin pearls and individual cell keratinization.
- *Grade II*—(Moderately differentiated, i.e. 25 to 50% anaplastic cells)—it is characterized by the presence of tumor cell exhibiting a wide range of differentiation, keratinization is occasionally present, and nuclear aberrations are moderately abundant. Usually, the invasion is poorly delineated from the stroma.
- *Grade III*—(Moderately differentiated, i.e. 50 to 75% anaplastic cells)—it is characterized by disorderly and poorly differentiated cells with no tendency towards keratinization, nuclear aberrations are abundant.

Fig. 5-6: Different routes of metastasis in the human body.

Fig. 5-7: Broader's classification (Grading System)—A diagrammatic representation

- **Grade IV**—(Poorly differentiated, i.e. more than 75% anaplastic cells)—in it, cells are so poorly differentiated that they cannot be identified as epithelial origin on the basis of histology alone, nuclear aberrations are abundant and no keratinization is found.

CIN Grading

Alternative classification for grading of dysplasia and carcinoma *in situ* together is cervical intraepithelial neoplasia (CIN). According to this grading, the criteria are as follows:

- **CIN I**—it represents less than 1/3rd involvement of the thickness of the epithelium.
- **CIN II**—in it, there is 1/3rd to 2/3rd involvement.
- **CIN III**—it is full thickness or equivalent to carcinoma *in situ*.

Depending on thickness of squamous epithelium involved by atypical cells

According to this, grading of dysplasia is as follows:

- Mild
- Moderate
- Severe

Staging

It is the extent of spread of tumor within patients.

Assessment

It is assessed by following ways:

- **Clinical examination**—staging can be assessed clinically by the size and extent of primary lesion.
- **Investigation**—investigation like radiology, sonography can lead to staging of disease.
- **Pathological examination**—this is very important part while staging of neoplastic process is done. Mainly biopsy, cytology are used.
- **Infiltration**—degree of infiltration of primary lesion should be carried out.
- **Metastasis**—presence or absence of metastasis to regional lymph nodes. Presence and absence of distant metastasis. Involvement of contralateral or ipsilateral node. Whether node are fixed or not.

Objectives

- **Treatment planning**—it aids clinician in the planning of treatment.
- **Prognosis**—to give some indication of prognosis.
- **Evaluation of treatment**—to assist in evaluation of the result of treatment.
- **Exchange of information**—to facilitate the exchange of information between treatment centers.
- **Investigation**—to contribute to the continuing investigations of human cancer.

TNM Staging

It is universally accepted system which is developed by UICC (Union Internationale Contre of Cancer).

- *Primary tumor (T)*: local extent is major factor contributing to prognosis.
 - T_x: primary tumor cannot be assessed.
 - T₀: no evidence of primary tumor.
 - T_{is}: carcinoma *in situ*.
 - T₁: tumor 2 cm or less in diameter.
 - T₂: tumor 2-4 cm in diameter.
 - T₃: tumor more than 4 cm in greatest diameter.
 - T₄: tumor of any size in which tumor invades adjacent structure (e.g.: cortical bone, inferior alveolar nerve, floor of mouth, skin of face etc).
- *Regional lymph nodes (N)*
 - N_x: regional lymph node cannot be assessed.
 - N₀: no regional lymph node metastasis.
 - N₁: metastasis in single ipsilateral lymph node less than 3 cm in diameter.
 - N_{1a}: nodes considered not contain to tumor growth.
 - N_{1b}: nodes considered to contain growth
 - N₂: single lymph node, no more than 6 cm in greatest dimension, of bilateral / contralateral lymph node, no more than 6 cm.
 - N_{2a}: Single ipsilateral lymph node more than 3 but less than 6 cm.
 - N_{2b}: multiple ipsilateral lymph nodes less than 6 cm.
 - N_{2c}: Bilateral or contralateral lymph node less than 6 cm in greatest dimension.
 - N₃: metastasis in lymph node more than 6 cm and it is fixed.
 - N_{3a}—ipsilateral nodes at least one greater than 6 cm.
 - N_{3b}—bilateral nodes greater than 6 cm.
 - N_{3c}—contralateral nodes at least one greater than 6 cm.
- *Distant metastasis (M)*
 - M_x: Distant metastasis cannot be assessed.
 - M₀: No distant metastasis.
 - M₁: Distant metastasis.
 - Category M₁ may be further specified according to the notation.
 - Pulmonary—PUL
 - Osseous—OSS
 - Hepatic—HEP
 - Brain—BRA
 - Lymph nodes—LYM
 - Bone marrow—MAR
 - Pleura—PLE
 - Peritoneum—PER
 - Skin—SKI
 - Other—OTH

AJC (American Joint Committee)

It divides all cancers into stage 0 to 4, and takes into account all three previous TNM systems.

- Stage 0—T₀ N₀ M₀
- Stage 1—T₁ N₀ M₀
- Stage 2—T₂ N₀ M₀
- Stage 3—T₃ N₀ M₀, T₁ N₁ M₀, T₂ N₁ M₀, and T₃ N₁ M₀
- Stage 4A—T₄ N₀ M₀, T₄ N₁ M₀, any T N₂ M₀
- Stage 4 B—Any T N₃ M₀
- Stage 4 C—Any T, Any N, M₁

Dukes ABC Staging

It is used in cancers of bowel

- *Stage A*—when tumor is confined to submucosa and muscle and cure rate is 100%.
- *Stage B*—tumor penetrates the entire thickness of bowel wall into pericolic or perirectal tissues and cure rate is 70%.
- *Stage C*—it is characterized by lymph node metastasis and reduces the cure rate to 30%.

STNMP Staging System

- *S—site of primary tumor*
 - S₁—lip and skin.
 - S₂—lip mucosa.
 - S₃—tongue.
 - S₄—cheek.
 - S₅—palate.
 - S₆—floor of mouth.
 - S₇—alveolar process.
 - S₈—antrum.
 - S₉—central carcinoma of bone.
- *Size of tumor—it is denoted by T*
 - T₁—less than 2 cm in diameter.
 - T₂—between 2 cm and 4 cm in diameter.
 - T₃—between 4 cm and 6 cm in diameter and extending beyond the primary region and extending through adjacent periosteum.
 - T₄—greater than 6 cm in diameter and extending to involve adjacent structures.
- *Regional nodes were grouped as*
 - N₀—no palpable nodes.
 - N₁—equifocal node enlargement.
 - N₂—clinically palpable homolateral regional nodes, not fixed.
 - N₃—same as N₂ but fixed.
 - N₄—clinically palpable contralateral or bilateral nodes, not fixed.
 - N₅—same as N₄ but fixed.
- *Metastasis*
 - M₀—no distant metastasis.

Differences between benign and malignant tumors

Features	Benign tumors	Malignant tumors
Macroscopic Features		
Boundaries	Encapsulated or well circumscribed	Poorly circumscribed and irregular
Surrounding tissues	Often compressed	Usually invaded
Size	Usually small	Often large
Growth	Slow and expanding	Rapid and infiltrating
Capsule	Present	Absent
Degeneration	Rare	Common
Recurrence	Not common	Common
Fixity	Absent	Present
Secondary changes	Occur less often	Occur more often
End of growth	May come to standstill	Growth rarely ceases
Microscopic features		
Pattern	Usually resemble tissue of origin	Have poor resemblance to tissue of origin
Basal polarity	Retained	Lost
Pleomorphism	Usually not present	Often present
Nucleo-cytoplasmic ratio	Normal	Increased
Anisonucleosis	Absent	Present
Hyperchromatism	Absent	Often present
Mitosis	May be present but always with typical mitosis	Mitotic figures are increased and are generally atypical and abnormal
Tumor giant cells	May be present but without nuclear atypia	Present with nuclear atypia
Cytoplasm	May show normal constituents	Normal cytoplasmic elements are decreased or lost
Function	Well maintained	May be retained, lost or become abnormal
Growth rate	Usually slow	Usually rapid
Local invasion	Often compresses the surrounding tissue without invading or infiltrating	Usually infiltrates and invades the adjacent tissue
Metastasis	Absent	Present frequently

- M₁—clinical evidence of distant metastasis without definite histological or radiographic conformation.
- M₂—proven evidence of metastasis beyond regional nodes.
- *Pathology of lesion*
 - P₀—hyperkeratotic lesion showing atypia.
 - P₁—carcinoma in situ.
 - P₂—basal cell carcinoma.
 - P₃—verrucous carcinoma.
 - Well differentiated sq. cell carcinoma.

- Moderately differentiated sq. cell carcinoma.
- Poorly differentiated sq. cell carcinoma.

Infection Control in Dental Office

Introduction

In dental practice, the risk of infection is a high priority issue, considering the nature of oral environment which is rich in diverse aerobic and anaerobic bacterial flora and more hazardous viral pathogens. Dental personnel and patients are at increased risk of acquiring many diseases which can get transferred from patient to doctor and vice versa. With changing times, risk associated with viral pathogens such as herpes, hepatitis and HIV are increased. The common goal of infection control is to eliminate or reduce the number of microbes shared between people.

Many objects in the dental office are potential source of infection. These are called as '*vectors*'. For examples; saliva, blood, nasal secretion, dust, hands, hair, clothing, films, X-ray machine, dental instrument and dental chairs. Cross infection occurs when these vectors transmit pathogenic organisms from one patient to another or to dental personnel.

All patients should be treated using universal precaution. There should be no exception and no extra precaution for specific patients. By practicing infection control, patients as well as operator can be protected.

High standard of dental infection control and occupational safety must be followed by dental personnel; for the safety of patient and dental health care workers. The word infection control does not mean total prevention of iatrogenic, nosocomial or occupational exposure, but it means to reduce the risk of disease transmission.

General Consideration

Every person working in hospital or general practitioner has a legal duty to ensure that all necessary steps are taken to prevent cross infection protect themselves, their colleagues and the patients.

Effective infection control measures are required in dental radiography even though most investigations are non-invasive or non-exposure prone and they do not involve breaches of the mucosa or skin.

Every patient in the department should have current medical history. Information gained by the history will alert the dental team about high risk situation.

In dentistry, infection can occur due to any of the following:

- *Salivary contamination*—the main risk from cross infection is due to salivary contamination from one patient to another or from working areas and equipments.
- *Contaminated object*—indirect contact with contaminated objects or instrument can occur.
- *Airborne infection*—direct contact with airborne contaminant present in spatter or aerosols or oral and respiratory fluids.

Identification of the risk and the presence of these infections is achieved by recording and keeping updated medical history. But, this cannot be relied on as:

- Patient may be unaware that they are infected. 50% of hepatitis B cases are asymptomatic and up to 10% become carrier.
- Patients may not have understood the diagnosis given to them by their medical practitioner.
- Patient may be incubating the infection.
- Information may be deliberately withheld.

It is therefore safer for HCW (health care worker) to accept that all patients can be infectious and age or class of the patient is no excuse.

Routes of Infection Transfer (Fig. 6-1)

- *Percutaneous*—this is high risk route. In this, transfer of microbes from saliva and blood can occur through needles and sharp instruments.

- **Contact**—this is also high risk transmission. In this, touching or exposing non-intact skin to infective oral lesion, infected tissue surface or infected fluids, splash and spatter of infected fluids.
- **Inhalation**—this is moderate risk transmission. In this, inhalation of aerosol or droplet containing pathogen can occur. Pathogens suspended in air from handpiece and droplet nuclei from coughing.
- **Through fomites**—it is low risk. It is very rare to touch contaminated inanimate surface in dental room or operation.

Fig. 6-1: Different routes of infection transfer

Infection of Main Concern

- **Infective hepatitis**—it includes mainly hepatitis B or hepatitis C. Risk group include IV drug user, heterosexual with multiple partners, homosexual, mentally subnormal patients and hemodialysis patient. 2% of the populations are known carriers of HBV which can be transmitted by saliva.
- **HIV and AIDS**—It is caused by HIV virus. Risk group include homosexuals, heterosexual with multiple partners, IV drug users, and patient with hemophilia. Most people are not aware of it at the time of infection and it may take 10 years or longer for AIDS to develop.
- **Herpes simplex infection**—Cold sores caused by herpes simplex infection are very infectious. There are chances of contracting herpetic whitlow, i.e. painful finger infection.
- **Tuberculosis**—it is caused by mycobacterium tuberculosis. If there is active infection, it may get transfer from saliva to the dentist.

Infection Risk Patients

- Patients who are HBs antigen positive and HBe antigen negative.
- Established cases of AIDS or AIDS related diseases like hairy leukoplakia, atypical ulceration and Kaposi's sarcoma.
- Patients who are HIV antibody positive.
- Patients who use IV drugs or other risk activities.

Methods of Decontamination

- **Sanitization**—this is first level of decontamination. This is process of physical cleaning to reduce quantity of microbes. This is done by cleaning the surface with soap and water or with detergent.
- **Disinfection**—this is next level of decontamination. It kills all vegetative microorganisms, fungi. This uses chemical germicides, radiation, ultraviolet rays or heat.
- **Sterilization**—this is third level. Sterilization kills all bacteria, fungi, virus and bacterial endospores. It uses chemical methods and physical methods.

Classification of Surface for Infection Control

According to Spaulding's classification in dental radiography is as follows:

- **Critical surface**—this is a surface that penetrates the tissue and contact blood. Examples are, scalpel blades, burs, extraction forceps, files, periodontal instruments, surgical drains, dental explorer, periodontal probes, biopsy punch, surgical drains, endodontic file reamer and implants. In this case, sterilization is done with the help of autoclave, chemical, dry heat.
- **Semi-critical surface**—this is the surface which does not penetrate tissue but contact with mucous membrane. It includes mouth mirrors, handpiece, anaesthetics syringe, chip syringes, amalgam condenser, impression trays, air/water syringe tips and high volume evacuator tips. In this case, high level disinfection and sterilization is required or barrier should be used.
- **Non-critical**—this includes the surface which penetrates neither tissue nor contact with mucous membrane. There is only contact with intact skin. It includes chair light handles, instrument trays, high touch work surface, bracket tales, chair control and dental chairs. In this case intermediated level of disinfection and sterilization is required. It is done by hydrogen peroxide bases, phenols, idophores.
- **Environmental surface**—this does not contact with patient directly. They can be contaminated by the care provider. It includes floor and door handles. In this case, sanitization should be properly done.

Working Area

The best method to reduce microorganism transfer is, to touch as few areas as possible.

- *Preparation of area*—the entire surface that is touched during radiography, should be covered with plastic wrap, plastic backed paper or aluminum foil. Covering eliminates the need for surface disinfectant after radiography.
- *After treatment*—if working area is not covered by protective covering, then after treatment of each patient, dental unit surface can become contaminated with blood and saliva. Operator should avoid touching walls and other surfaces with contaminated gloves. This area should be thoroughly cleaned with disposable towel.
- *Material used*—to clean working surface disinfecting solution is sprayed and allowed to dry. Most commonly used disinfectant is phenolic, idophores and chlorine containing compounds.

Sterilization

Sterilization is the process of destroying all the microbial life from an article or surface inclusive of bacterial spores. It can be achieved by:-

Dry Heat

It denatures the proteins of a microorganism rendering them non-viable. This principle is applied in the hot air oven. The instruments are packed loosely inside the oven and a temperature of 160°C is achieved with a holding time of 1 hour.

The hot air oven is exclusively used for sterilizing glass articles, oils, greases and powders. The other physical methods include microwave and ultraviolet methods (Fig. 6-2).

Moist Heat

Moist heat denatures and coagulates the proteins of a microorganism and is a better method of sterilization due to a higher efficiency of penetration than dry heat and a faster killing rate. This is due to latent heat of vaporization which is present in moist heat. This principle is used in the autoclave (Fig. 6-3).

Various methods of autoclaving are available base on the same principle. The temperature required for this is 121°C with a minimum holding time of 20 minutes. For practical consideration, vacuum models are operated at a temperature of 139°C, 332lb pressure and holding time of 5 minutes.

Fig. 6-2: Ultraviolet sterilizer.

Fig. 6-3: Autoclave used in dentistry.

Fig. 6-4: Formalin chamber.

For gravity displacement models, a temperature of 121°C, 20lb pressure and a holding time of 30 minutes are used.

Root canal instruments and burs can be washed and thereafter sterilized in a glass bead sterilizer at a temperature of 210-230°C. The specific disadvantage of this sterilizer is that the handle portion is not sterilized and therefore, these articles are not entirely sterile.

Chemical (Fig. 6-4)

Ethylene oxide—this is a toxic gas that can be used to sterilize heat sensitive equipments. The articles are to be packed dry prior to sterilization otherwise a thin film of toxic ethylene glycol is formed. After sterilization, the articles should be aerated for at least 24 hours before use for dissipation of residue of the gas which could cause haematological complications. These are suited for large institutions and may not be a feasible option where small establishments are involved.

Glutaraldehyde—it is being marketed as a 2% solution which has to be activated with an alkali which is provided with the product as an activator, as only the alkaline solution is effective. The solution should have a contact time of at least 6 hours. A lesser contact time is employed for disinfection will not be effective against spores.

Disinfection

This is the process by which pathogenic microorganisms are removed from the surface without removing bacterial spores. This process is used to treat articles which do not penetrate mucous membrane or skin. Examples of disinfectants are formaldehyde, halogens, phenols and chlorhexidine.

Infection Control Procedures

The basis for infection control lies in the fact that, as dentist are more prone to acquire many infectious diseases; including blood borne diseases such as AIDS and hepatitis B. The procedure for infection control can be grouped into six major areas:

Training

All the staff members should be given training of infection control procedure. They should be told about the hazards due to infection which can occur to them or get transferred from them to patients. Continued education programme about infection control measures should be held regularly.

Vaccination

This is very important in infection control procedure. All clinical staff should be vaccinated against hepatitis B, etc. and regularly get it checked.

Covering of Wound

Open wound on the hand should be covered with waterproof dressing. Hand injuries during dental procedure should be avoided.

Hand Washing

It provides protection to both the patients and the dental team. Hand washing continues to be an important means for personal protection and of disease prevention. Washing hands before gloving reduces the skin microbial flora and helps to prevent skin irritation by waste products of bacterial growth under gloves.

Gloved hands should be washed under running water before and after taking radiograph of patient and a disinfectant like povidone iodine and 7.5% surgical scrubs or chlorhexidine gluconate 4% surgical scrub should be used.

Hand washing should be done at the start of treatment and after removing the gloves. Hand washing after using gloves is required to reduce the bacterial count that build on the skin during glove used. Specific step should be taken to hand wash. They are as follows (Fig. 6-5).

- Wet hands with warm water.
- Dispense an adequate amount of soap.
- Thoroughly rub the hands including area around the thumb and finger for 30 seconds.
- Wash hand with warm water to remove the soap.
- Dry hands with proper towel.

Fig. 6-5: Hand should be properly washed before gloving.

Gloves

Gloves used for patient care protect the dental team members from direct contact with patient microbes and they protect patients from contact with microbes on the hands of dental team member. Gloves need to be changed between patients and are to be washed with detergent. Gloves should be inspected periodically during patient care and torn or punched gloves should be removed as soon as possible and the hands should be washed.

Although some of these types, i.e. utility gloves can be autoclaved (nitrile type) through washing with an antimicrobial hand washing agent followed by rinsing and towel drying is adequate between routine uses.

Exam gloves are made from latex, vinyl, nitrile and polyurethane. While wearing the gloves, you should look for breaches in the integrity of gloves. Gloves should never be washed before use or disinfected for reuse. Grubby gloves and cleaning swabs should be placed in suitable disposable bags and sealed for incineration.

Fig. 6-6: Doctor should always wear double gloves while examination of the patient.

Protection against Aerosol and Spatter

It involves the use of a pre-procedural rinsing of the patient's mouth with an anti-microbial solution, use of rubber dam, high volume evacuation, protective clothing and eyewear.

Reduce the amount of spray and spatter that exist in a patient's mouth during care, which in turn reduce the number of microbes contaminating the dental team.

Rubber dam (Fig. 6-7) has been shown to reduce the number of microbes in dental aerosols generated during operative procedures and saliva ejection minimizes saliva form accumulating in the mouth.

Fig. 6-7: Rubber dam should be used to control dental aerosols generated during operative procedure.

Having patient rinse their mouth with an antimicrobial mouth rinse just before care, will reduce the number of bacteria that exist in the mouth.

Eyewear and face shield—eyewear and face shields with adequate side protection prevent spatter from patient's mouth or splashes of contaminated solution and chemicals from contacting eyes (Figs 6-8 and 6-9).

Fig. 6-8: Dental professional should wore eyewear to prevent spatter from patient mouth.

Masks—face masks prevent spatter from patient's mouth or splashes of contaminated solution and chemicals from contacting the mucous membrane of mouth and nose. A secondary protective aspect of a mask is the reduction in the inhalation of airborne particles. Thus, masks should be worn whenever there is a risk of aerosol generation, spraying, spattering, or splashing of patient's oral fluid or chemicals used (**Fig. 6-10**).

Fig. 6-9: Complete face shield also help to protect from aerosols from patient oral cavity.

Protective clothing—as with eyewear and masks, protective clothing is also worn under conditions generating sprays, spatters, splashes or spills of body fluids, contaminated solutions. Protective clothing is the outer layer covering the garment that would first be contacted by the contaminating droplets. Such fluid resistant garments for use at chair side in dentistry may be reusable or disposable but it should protect the skin and underlying clothes from

Fig. 6-10: While examining the patient, dental professional should wear mask, gloves.

exposure to potentially infectious material. This protection can be provided by high-neck, long sleeved, knee length garments.

Instrument Asepsis

You should provide instruments that are safe for patient's use. Pre-soaking of contaminated instruments keeps them wet until thorough cleaning can occur. This procedure prevents blood and saliva from drying on the instrument which facilitate cleaning.

A cleaning solution manufactured for use in ultrasonic cleaners should be used and it needs to be changed daily. Protection against splashing and direct contact with this contaminated solution is important. Usually 2 to 20 minutes are needed to clean instruments ultrasonically as determined by observing the cleanliness of the processed instruments and making appropriate adjustments.

After cleaned instruments have been rinsed and dried, they are to be packaged in functional sets before sterilization. Instrument packages sterilized in steam becomes wet and must be allowed to dry before handling so that the packing does not tear.

Surface Asepsis

It eliminates the involvement of surface in the spread of diseased agents.

There are two general approaches to surface asepsis. One is to clean and disinfect contaminated surface and the other is to prevent the surface from becoming contaminated by use of surface covers.

Disinfection of surfaces involves the cleaning of surface after every patient and application of a disinfectant chemical. These chemicals include alcohol, phenols, glutaraldehyde, chlorine etc.

Spittoons should be flushed with water.

Management of Sharp and Other Waste Products

It reduces the chances for sharp injuries and contact with potentially infectious materials. There should be safe handling of needles and safe removal of needles. Needles should not be recapped instead, should be disposed off directly. Handpiece should not be left in position with burs; instead the bur should be removed after use. Infectious waste is preferably done by incineration.

Aseptic Technique

It includes aseptic retrieval of supplies, reducing contamination from dental unit water supplies, aseptic radiographic procedures.

Section **2**

Diagnostic Procedures

7

Case History

Introduction

A case history can be considered to be a planned professional conversation that enables the patient to communicate his symptoms, feeling and fears to the clinician so that the nature of the patient's real and suspected illness and mental attitudes may be determined.

The interest, warmth and compassion exhibited by the dentist are important factors in establishing patient rapport and in obtaining meaningful history. A kind and considerate approach is most important in securing and gaining the confidence of the patient. Indicate the patient that you are a friend who is keenly interested in him/her as a person.

Ideally the patient's history should be taken in a consultation room or a private office in which the décor and the furnishing are quite different from those of the dental operatory. The friendly atmosphere is an important factor in helping the patient to talk freely about his problems (Fig. 7-1).

Fig. 7-1: Taking and recording history of the patient is important part in diagnostic sequence.

Diagnostic Procedure (Fig. 7-2)

The procedure can be divided into:-

- Personal information.
- Taking and recording history.
- Examining the patient.
- Establishing a provisional diagnosis on the basis of history and examination.
- Conducting the necessary investigation.
- Formulation of final diagnosis on the basis of the results of the investigations.
- Making a plan of treatment and medical risk assessment for dental patient

Personal Information

Name

A patient usually likes to be called by name. This will help to elicit the history properly, but it will also be of psychological benefit to the patients. In case of pediatric patients, addressing the patient by his/her name or pet name will encourage him/her to talk freely. Advantage of knowing the patient names are identification, to maintain record, communication and psychological benefit

Age

Knowing the patient's age is beneficial to the clinician in more ways than one.

Diagnosis

Certain diseases are more common at certain ages (Tables 7-1 to 7-4).

Treatment Planning

- *Absence of teeth*—if there is complete absence of teeth (i.e. true anodontia) even at the age of 4-5 years; it is most

Fig. 7-2: Diagrammatic representation of diagnostic procedure of case history.

frequently in association with hereditary ectodermal dysplasia.

- **Delayed eruption**—delayed eruption of teeth may be associated with rickets, cretinism or certain local factors such as fibromatous gingivae. If the permanent tooth does not erupt in its eruption period, we have to check by radiograph whether the permanent tooth bud is present or not. If the bud is present, deciduous tooth should be extracted.
- **Ankylosed deciduous teeth**—ankylosed deciduous teeth prevent the eruption of permanent teeth; in such cases,

ankylosed teeth should be removed surgically to prevent the development of malocclusion, local periodontal disturbances and dental caries.

- **Behavior management technique**—it differs according to the age of the patient. In case of pediatric patients, the dentist has to deal with the child as well as with the parent; hence in pediatric dentistry, the approach is 1:2; while in case of adults, the approach is 1:1. In talking to a child, the dentist must get down to the patient's own level, in position and in conversation. Child patients may be intelligent or retarded.

Table 7-1: Disease present at/since birth

DENTAL DISEASES**Related to jaw**

- Agnathia
- Facial hemihypertrophy
- Macrognathia
- Cleft palate
- Facial hemiatrophy

Related to lip

- Commissural pits and fistulae
- Double lip
- Cleft lip
- Hereditary intestinal polyposis syndrome

Related to gingiva

- Congenital epulis of the newborn
- Fibromatosis gingiva

Related to rest of oral mucosa

- Pigmented cellular nevus
- Cystic hygroma
- Fordyce's granule

Related to tongue

- Microglossia
- Macroglossia
- Aglossia
- Ankyloglossia
- Cleft tongue
- Fissured tongue
- Median rhomboidal glossitis
- Lingual thyroid nodule

Related to salivary glands

- Aplasia
- Atresia
- Aberrancy
- Developmental lingual salivary gland depression

Related to teeth

- Pre-decidual dentition

Related to TMJ

- Aplasia or congenital hypoplasia of the mandibular condyle

Others

- Teratoma
- Erythroblastosis fetalis
- Hemophilia

SYSTEMIC DISEASES**Related to heart**

- Atrial septal defect
- Patent ductus arteriosus
- Ventricular septal defect
- Pulmonary stenosis
- Aortic stenosis
- Tetralogy of Fallot

Related to respiratory system

- Bronchiolitis
- Cystic fibrosis

Related to CNS

- Congenital myopathy
- Aqueduct stenosis

Related to alimentary tract

- Meckel's diverticulum (it is common congenital anomaly. It is a small hollow wide mouthed sac protruding from ileum)
- Annular pancreas (pancreas encircle the 2nd and 3rd part of duodenum leading to gastric outlet obstruction)

Table 7-2: Diseases more commonly seen in infancy

Dental/oral/systemic diseases with oral manifestations

- Palatal cyst of the newborn
- Heterotrophic oral gastrointestinal cyst
- Hemangioma
- Fibrosarcoma
- Hemangioendothelioma
- Hemangiopericytoma
- Embryonic rhabdomyosarcoma
- Melanotic ameloblastoma
- Dental lamina cyst of the newborn
- Hurler's syndrome
- Acute suppurative osteomyelitis of the jaw
- Letterer-Siwe disease
- Progeria
- Infantile cortical hyperostosis of the jaw
- Fibrous dysplasia of the jaw
- Sprue
- Thalassemia

Systemic diseases

- Congenital heart diseases
- Bronchiectasis
- Pneumonia

- *Child dose*

$$\text{Young rule} = \frac{\text{Child's age}}{\text{Age} + 12} \times \text{adult dose}$$

$$\text{Clark rule} = \frac{\text{Child age at next birth day}}{24} \times \text{adult dose}$$

$$\text{Dilling rule} = \frac{\text{Age}}{20} \times \text{adult dose}$$

Sex

- *Diagnosis*—certain diseases are more common in a certain sex (**Tables 7-5 and 7-6**).
- *Gifting*—in case of pediatric patients, gifting varies according to the sex of the child.
- *Esthetics*—females are much conscious about esthetics.
- *Emotion*—females are emotional and sensitive hence one must be very careful during treatment. Failure to thrive, educational and emotional abuse are most common in case of female patients.
- *Child abuse*—sexual abuse or exploitation is more common in case of females.
- *Dose*—females have smaller body weight and require lower dose as compare to males.
- *Drug interaction*—in females, consideration must be given to menstruation, pregnancy and lactation. Drugs given during pregnancy can affect the fetus. Antihypertensive drugs interfere with sexual function in males but not in females. Gynecomastia is a side effect of ketoconazole, metronidazole, chlorpromazine and digitalis administrations that occur in males. Ketoconazole causes loss of libido in men but not in women.

Table 7-3: Diseases frequently seen in children and young adults**Dental/oral/systemic diseases with oral manifestations**

- Focal epithelial hyperplasia
- Retrocuspid papilla
- Fissured tongue
- Benign migratory glossitis
- Benign cervical lymphoepithelial cyst
- Epidermoid and dermoid cyst
- Papilloma
- Papillon-Lefèvre syndrome
- Peripheral ossifying fibroma
- Juvenile periodontitis
- Naso-alveolar cyst (12-75 years)
- Thyroglossal duct cyst
- Oral submucous fibrosis (20-40 years)
- Osteoid osteoma of the jaw
- Benign osteoblastoma of the jaw
- Torus palatinus
- Kaposi's sarcoma
- Ewing's sarcoma
- Osteosarcoma of the jaw
- Primary lymphoma of bone
- Burkitt's lymphoma
- Hodgkin's disease
- Rhabdomyosarcoma
- Alveolar (soft part) sarcoma
- Pleomorphic adenoma
- Central odontogenic fibroma
- Odontogenic myxoma (2nd and 3rd decade)
- Peripheral cemental dysplasia
- Benign cementoblastoma
- Dentinoma
- Ameloblastic fibro-odontoma
- Reiter's syndrome (20-30 years)
- Chronic focal sclerosing osteomyelitis of the jaw
- Chronic osteomyelitis with proliferative periostitis of the jaw
- Basal cell carcinoma
- Lymphoepithelial cyst
- Lingual varices
- Sq. cell carcinoma
- Scarlet fever
- Diphtheria
- Sarcoidosis
- Nasopharyngeal angiofibroma (16 years)
- Chondromyxoid fibroma (under 25 years)
- Benign chondroblastoma of the jaw (5 to 25 years)
- Osteoma of the jaw (young adult)
- Rickets
- Sickle cell anemia
- Infectious mononucleosis
- Acute leukemia
- Pemphigus
- Noma
- Primary herpetic stomatitis
- Recurrent aphthous stomatitis
- Acute lymphonodular pharyngitis
- Dental caries
- Nursing bottle caries (children)
- Pulp polyp
- Eruption cyst
- Dentigerous cyst (2nd decade)

Systemic diseases

- | | |
|-----------------------------|-----------------------------|
| • Congenital heart diseases | • Rheumatoid heart diseases |
| • Asthma | • Acquired bronchiectasis |
| • Pneumonia | • Jaundice |
| • Smallpox | • Juvenile diabetes |
| • Typhoid | • Cretinism |

Table 7-4: Diseases frequently seen in adults and older patients**Dental/oral/systemic disease with oral manifestation**

- | | |
|--|--|
| • Attrition | • Abrasion |
| • Gingival recession | • Periodontitis |
| • Acute necrotizing ulcerative gingivitis | • Dentinal sclerosis |
| • Pulp stone and fibrosis | • Cementicles |
| • Root resorption | • Atrophic diffuse sclerosing osteomyelitis of the jaw |
| • Lichen planus | • Leukoplakia |
| • Leukoedema | • Erythroplakia |
| • Carcinoma <i>in situ</i> | • Sjogren's syndrome (over 40 years) |
| • Adenoid cystic carcinoma | • Mucoepidermoid carcinoma |
| • Acinic cell carcinoma | • Gingival cyst of the adult |
| • Necrotizing sialometaplasia | • Primary intra-osseous carcinoma of the jaw |
| • Ameloblastoma (30-50 years) | • Macroglobulinemia |
| • Adenoameloblastoma | • Ameloblastic fibrosarcoma |
| • Sq. odontogenic tumor | • Carcinoma of gingiva |
| • Peripheral odontogenic fibroma | • Spindle cell carcinoma |
| • Trigeminal neuralgia | • Orolingual paresthesia |
| • Verrucous carcinoma | • Glossopharyngeal neuralgia |
| • Adenoid sq. cell carcinoma | • Malignant melanoma |
| • Sphenopalatine neuralgia | • Peripheral giant cell granuloma (30 years) |
| • Temporal arteritis | • Median anterior maxillary cyst (40-60 years) |
| • Fibroma | • Nasoalveolar cyst |
| • Carcinoma of lip, tongue, floor of mouth and buccal mucosa | • Lingual cyst (7-99 years) |
| • Keratoacanthoma (50-70 years) | • Herpes zoster |
| • Lymphoepithelial cyst (15-65 years) | • Pernicious anemia |
| • Basal cell carcinoma | • Osteomalacia |
| • Chronic leukemia | • Canicular adenoma |
| • Iron deficiency anemia | • Adenolymphoma |
| • Pleomorphic adenoma | • Hereditary hemorrhagic telangiectasia |
| • Oxyphilic adenoma | • Osteoma of jaw bone |
| • Lipoma | • Fibrosarcoma of jaw bone |
| • Myxoma of jaw bone | • Hodgkin's disease |
| • Chondroma of jaw bone | • Solitary plasma cell myeloma |
| • Torus mandibularis | • Malignant schwannoma |
| • Liposarcoma of jaw bone | |
| • Multiple myeloma | |
| • Leiomyoma | |
| • Olfactory neuroblastoma | |

Systemic diseases

- | | |
|--|--|
| • Diabetes | • Hypertension |
| • Hypotension | • Congestive cardiac failure and myocardial infarction |
| • Renal failure | • Chronic valvular heart disease |
| • Atherosclerotic diseases like angina pectoris and coronary heart disease | • Hepatitis |
| • Peptic ulcer | • Asthma |

Table 7-5: Diseases more common in females

- | | |
|--------------------------------|---------------------------------------|
| • Iron deficiency anemia | • Caries |
| • Diseases of thyroid | • Pleomorphic adenoma |
| • Sjogren's syndrome | • Adenoameloblastoma |
| • Central cementifying fibroma | • Myasthenia gravis |
| • Torus palatinus | • Peripheral cemental dysplasia |
| • Sickle cell anemia | • Juvenile periodontitis |
| • Cicatricial pemphigoid | • Recurrent aphthous stomatitis |
| • Malignant melanoma | • Peripheral giant cell granuloma |
| • Central giant cell granuloma | • Peripheral ossifying fibroma |
| • Nasoalveolar cyst | • Idiopathic thrombocytopenic purpura |

Table 7-6: Diseases more common in males

• Attrition	• Caries in deciduous teeth
• Carcinoma <i>in situ</i>	• Carcinoma of the buccal mucosa
• Keratoacanthoma	• Basal cell carcinoma
• Leukoplakia	• Adenoid cystic sq. cell carcinoma
• Verrucous carcinoma	• Multiple myeloma
• Liposarcoma	• Chondrosarcoma
• Hodgkin's disease	• Herpes simplex
• Solitary plasma cell myeloma	• Ewing's sarcoma
• Wegener's granulomatosis	• Ameloblastic fibro-odontoma
• Osteoid fibroma	• Basal cell adenoma
• Benign osteoblastoma	• North American blastomycosis
• Reiter's syndrome	
• Adenolymphoma	
• Pernicious anemia	

Address (Residence)

- **Correspondence**—it is necessary for future correspondence. Full postal address of the patient should be taken for future communication.
- **Geographical prevalence of dental/oral diseases**—a few diseases have got geographical distribution. *Dental caries* and *mottled enamel* are dependent on the fluoride content of the domestic water. In India, *cancer of the lip* is very rare and *cancer of tongue* and *buccal mucosa* constitute the bulk of oral cancers. In cancer patients from *Mumbai*, common site affected is the tongue and in *Chennai*, it is the buccal mucosa. *Dental caries* is more common in modern industrialized areas while *periodontal diseases* are more common in rural areas. Habits also vary according to residence. Chutta, a form of tobacco, is common in *Tamilnadu*, gutkha in *Bihar*, hukli in *Bhavnagar district of Gujarat*. Bajjar is a dry snuff used by women in *Gujarat*.
- **Geographical prevalence of medical disease**—there are many medical diseases which have got geographical prevalence. For example *filariasis* (*Orissa*), *leprosy* (*Bankura district of West Bengal*), *gall bladder disease* (*West Bengal and Bangladesh*), *peptic ulcer* (*North Western and Southern parts of India*), *sleeping sickness* (*South Africa*), *hydatid disease* (*Australia*), *tropical disease* (*tropical countries*), *kangri cancer* (*Kashmir*), *anemia and malnourishment* (*rural areas*) *obesity, arthrosclerosis* (*urban area*) and *other industry related diseases* (*urban areas*).

Registration Number

It is good to give each and every patient a unique registration number and to maintain his/her records under that number so that when the patient visits the doctor at a later date, the doctor can know the details of the patient and the treatment done before.

Occupation

- **Financial status**—treatment varies according to the financial status of the patient. Expensive treatment

cannot be given to the patient with low socio-economic status.

- **Disease**—some diseases are peculiar to certain occupations:
 - **Attrition**—Certain occupations, in which the worker is exposed to an atmosphere of abrasive dust and cannot avoid getting the material into his mouth, causes severe attrition. Habitual opening of the pins may result in notching of the incisal edge.
 - **Abrasion**—it is commonly noted in carpenters, shoemakers or tailors who hold pins, nails or tacks between their teeth.
 - **Gingival staining**—the strange dark stippling of the marginal gingiva is seen in patient works with lead, bismuth or cadmium.
 - **Erosion**—undue erosion of teeth is seen in sandblaster, who should be promptly referred to his physician for pulmonary silicosis.
 - **Hepatitis-B**—dentists, surgeons, blood bank personnel etc. are very prone to hepatitis -B.
 - **Chelitis glandularis**—in occupations where there is chronic exposure to sun, wind and dust can cause cheilitis glandularis.
 - **Varicose veins**—it is common in bus conductors and traffic policemen.
 - **Urinary bladder neoplasm**—it is common in aniline dye workers.
 - **Carcinoma of scrotum**—it is common in chimney sweepers or those who work in tar and oil companies.
 - **Medial semilunar cartilage injury**—injury to the medial semilunar cartilage of the knee occurs in football players and miners.
 - **Student elbow**—enlargement of certain bursae may occur from repeated friction of the skin over the bursae like in 'student's elbow', 'tennis elbow' and 'house-maid knee'.
 - **Mesothelioma**—an ice cream vendor may have mesothelioma due to exposure to asbestos for many years.
 - **Stress disease**—certain occupational hazards are associated with office work, e.g. repetitive strain injury and migraine induced by stress of inappropriate lighting.
 - **Cirrhosis of liver**—barmen who have ready access to alcohol have high mortality for cirrhosis of liver and tuberculosis.
 - **Countryman's lip**—carcinoma of lip is commonly seen in persons who have to do outdoor work and that's why, it is called as 'countryman's lip'
- **Time**—In case of pediatric patients, if both the parents are working and even if they are aware of the importance of dental health, they cannot properly attend the appointments given by the dentist.

Religion

- *Carcinoma of penis*—it is hardly seen in Jews and Muslims owing to their religious custom of compulsory circumcisions of penis.
- *Phimosis*—for the same reason phimosis, subprepuical infection etc are not seen in them.
- *Intussusception*—on the other hand intussusception is sometimes seen after the month long fast in Ramjan in Muslims.

Taking and Recording History

Chief Complaint

- *Definition*—it is the patient's response to the dentist's questions. Chief complaint is the reason for which the patient has come to doctor or the reason for seeking the treatment. The chief complaint should be recorded in the patient's own words and first attention should be given to it.
- *Chronological recording*—each of these complaints should be recorded in chronological order. If few complaints start simultaneously, record them in the order of severity.
- *Do not interrupt*—do not interrupt the patient if possible.
- *Significance*—chief complaint aids in the diagnosis and treatment planning.
- Most common chief complaints and their causes are described in **Table 7-7**.

History of Present Illness

- *Collecting information*—the history commences from the beginning of the first symptom and extends to the time of examination. Information should be collected by asking the following questions:
 - When did the problem start?
 - What did you notice first?
 - Did you have any problems or symptoms related to this?
 - Did the symptoms get better or worse at any time?
 - What you done to treat these symptoms?
 - Have you consulted anyone else for this problem?
- *Mode of onset*—it can be sudden or gradual. It should be in terms of time, in days, weeks, months, before the current appointment.
- *Cause of onset*—one has to determine whether if any thing that the patient has experienced may have precipitated the signs and symptoms.
- *Duration*—it should be noted that, since how many days complaint was present.
- *Progress*—it may be described as intermittent, recurrent, constant, increasing or decreasing in severity. Aggravating and alleviating factors should be noted.

- *Relapse and remission*—this should be noted. If patient has got any similar complaint in the past and then again it relapse.
- *Treatment*—if the patient has taken any treatment for the same problems, the mode of treatment and doctor who has treated the patient should be recorded.
- *Negative history*—e.g. in case of sinus on the cheek absence of the history of watery discharge at the time of meals excludes the possibility of the parotid fistula.

History with Particular Reference

Pain (Fig. 7-3)

- *Anatomical location where the pain is felt*—the patient should be asked to point to the area affected and outline the way in which the pain may spread to affect other areas. He should be asked whether the pain is deep or superficial.
- *Origin and mode of onset*—the onset may be wholly spontaneous. It may be induced by certain activities like yawning, chewing, drinking hot and cold liquids etc. It may be triggered by minor stimulation such as touch or movement of skin, lip and tongue.

Fig. 7-3: History of the patient in particular reference to pain.

Table 7-7: Most common complaints and their causes

Pain - Gingival and periodontal disease - Pulpal disease - Mucous membrane disease - Salivary gland infection - Lesions of jaw bones - Lymph node inflammation - TMJ disorder - Maxillary sinus disease - Ear disease - Psychosis - Angina pectoris - Tonsillar disease - CNS disease - Neuralgia - Neuritis - Esophageal diverticulum - Eagle's syndrome - Trotter's syndrome	- Trauma - Normal resorption of deciduous teeth - Pulpoperiodontal disease - Malignant tumor - Chondroma - Myxoma - Hemangioma - Histiocytosis X - Familial hypophosphatemia - Papillon-Lefèvre syndrome - AIDS	Bad taste - Aging changes - Heavy smoking - Poor oral hygiene - Dental caries - Periodontal disease - ANUG
Burning sensation - Idiopathic burning tongue - Psychosis - Neurosis - Viral infection - Fungal infection - Chronic bacterial infection - Geographic tongue - Xerostomic condition - Fissured tongue - Generalized oral mucosal disease - Anemia - Achlorhydria - Multiple sclerosis - Vitamin deficiency	Recent occlusal problems - Periodontal disease - Traumatic injury - Periapical abscess - Cyst and tumor of tooth bearing region of jaw - Fibrous dysplasia	Diabetes - Hypertension - Medication - Psychosis - Neurological disorder - Decreased salivary flow - Uremia - Intraoral malignancy
Bleeding - Gingivitis - Periodontal disease - Inflammatory hyperplasia - Allergy - Traumatized tumor - Hemangioma - Traumatic injury - Deficiency of coagulation factors	Delayed tooth eruption - Malposed or impacted teeth - Cyst - Odontoma - Sclerosed bone - Tumor - Mal-development - Cleidocranial dysplasia - Hypothyroidism	Paresthesia and anesthesia - Injury to regional nerve—anesthetic needle and jaw bone fracture - Malignancy - Medications like those used in sedation, hypnosis - Diabetes - Pernicious anemia - Multiple sclerosis - Acute infection of jaw bones - Psychosis
Loose teeth Periodontal disease	Xerostomia - Local inflammation - Infection and fibrosis of major salivary gland - Dehydration state - Drugs like tranquilizers and antihistaminic - Autoimmune diseases like Sjogren's syndrome and Mikulicz's disease - Chemotherapy - Post radiation changes - Psychosis Swelling - Inflammation and infection - Cyst - Retention phenomenon - Inflammatory hyperplasia - Benign tumor - Malignant tumor	Halitosis - Poor oral hygiene - Periodontal disease - Third molar opercula - Decayed tooth - ANUG - Oral cancer - Spicy foods - Tobacco use - Nasal infection - Tonsillitis - Pharyngeal infection and tumor - Gastric problems - Diabetes - Uremia

- Intensity of pain**—the intensity of pain should be established by differentiating between mild and severe pain. This will show how patient reacts to his suffering. Intensity can be recorded verbally or by some scaling method.
- Nature of the pain**—the general quality of the pain complaint should be classified as how it makes the patient feel. It can be burning, throbbing, scalding, shooting, stabbing, vague aching pain, splitting, dull, aching, lacerating, cutting, boring, constricting, gripping, scorching, pounding, heavy, pressing, sharp, bright, gnawing, cramping, squeezing, or searing.
- Progression of the pain**—the progression of pain should be noted.
- Duration of pain**—the duration of an individual pain episode is an important descriptive feature that aids in pain identification. A pain is said to be momentary if its duration is expressed in seconds. The pain that continues from one day to the next is said to be protracted.
- Movement of pain**—radiation of pain, referred pain and shifting or migration of pain.
- Localization behavior**—a determination of pain localization should be made in the description of the behavior. This includes whether the pain is localized or diffuse, radiating or spreading and enlarging or migrating.
- Effect of functional activities**—the effect of various activities such as talking, brushing of teeth, shaving, washing the face, turning the head, lying down, etc. should be noted.

The effect of tension, fatigue and the time of the day should also be noted.

- **Concomitant neurological signs**—the description of pain cannot be completed unless other sensory, motor and autonomic effects are included. Accompanying sensation of hyperesthesia, anesthesia or dysesthesia should be mentioned. Any concomitant change in the special senses affecting vision, hearing, smell or taste should be noted. Motor changes such as muscular weakness, muscular contraction should be described; likewise ocular signs, nasal signs, and cutaneous signs should be described.
- **Temporal behavior**—the temporal behavior of pain should be evaluated, whether the pain is intermittent or continuous. It should not be confused with the effect of medication that induces a period of comfort by analgesic action.
- **Others**—other point like special time of occurrence, periodicity of pain and precipitating factors and relieving factors should be noted.
- **Questions to be asked to the patient**—
 - Is the pain sharp and lacinating or dull aching and throbbing?
 - Does pain occur spontaneously or do certain activities cause it?
 - Is the pain constant or periodic?
 - Does the pain gradually build in intensity or it is paroxysmal?
 - Is the pain worse at any time of the day?
 - Is the pain of short duration or long?

Swelling (Fig. 7-4)

- **Duration**—since how many days swelling is present should be noted as it will determine its acute or chronic nature.
- **Mode of onset**
 - *Masses that increase in size just before eating*—salivary gland retention phenomenon.
 - *Slow growth*—reactive hyperplasia, chronic infection, cysts and benign tumors.
 - *Moderately rapid growing mass* (week to about 2 months)—chronic infection, cysts and malignancy.
 - *Rapidly growing mass*—abscess, infected cyst, aneurysm, salivary retention phenomenon and hematoma.
 - *Mass with accompanying fever*—infection and lymphoma.
- **Symptoms**—symptoms associated with swelling like pain, difficulty in respiration, swallowing or any other movement; disfiguring etc. In case of pain; nature, site and time of onset should be noted.
- **Progress of swelling**—swelling can increase gradually in size or rapidly.

- **Associated features**—fever, presence of other swellings and loss of body weight should be asked and noted.
- **Secondary changes**—like softening, ulceration, inflammatory changes.
- **Impairment of function**—nature of loss of movement and intensity.
- **Recurrence of the swelling**—if the swelling recurs after removal, it may indicate malignant changes. Cystic swelling may recur if the cyst wall is not completely removed.

Fig. 7.4: History of swelling should be taken properly.

Ulcer

- **Mode of onset**—mode of onset and duration of the ulcer should be asked and recorded.
- **Pain**—ulcers associated with inflammation are painful; ulcers associated with epithelial or basal cell carcinoma are painless.
- **Discharge**—serum, blood and pus.
- **Associated diseases**—tuberculosis, nephritis, diabetes, and syphilis.

Past Dental History

- *Patient attitude*—in addition to chief complaint and history of the present illness, it is necessary to elicit a past dental history. It is necessary to obtain description of the details of previous dental treatment and his reaction to his dentist and the treatment. By noting this, you may get accurate idea of the importance he gives to good dental treatment and how conscious he has been in pursuing a goal of good oral health.
- *Component of past dental history*—significant component of past dental history include previous restorative, periodontic, endodontic or oral surgical treatments, reasons for loss of teeth, untoward complication of dental treatment, experience with orthodontic appliance and dental prostheses; and radiation or other treatment for past oral and facial lesions.

Past Medical History

Obtaining the patient medical history is very important as it can assess the patient health status and also it can facilitate for the better diagnosis for the orofacial complaint of the patient. By taking proper medical history, following goal are achieved.

- *Assess in diagnosis of oral disease*—there are many systemic problems which have oral manifestation. So by taking medical history, we can come to diagnosis of many orofacial complaints. For example, in HSV infection, negative history of recurrent herpes labialis and positive history of close contact with patient with primary and recurrent herpes is helpful in making the diagnosis.
- *Detection of underlying systemic problems*—many times, patient is not aware of systemic problems due to his negligence. So by taking proper medical history, we can detect many systemic problems in the patient.
- *Management of patient*—by assessing the patient general status, we can determine our plan of treatment. As many systemic diseases can change our line of treatment while treating the dental complaint. So we can modify our treatment according to need.
- *Consultation with other professional*—by assessing the medical status, we can also determine whether any additional information is necessary to assess the patient medical status. Dentist may require consultation in following conditions:
 - *Known medical problems*—consultation is required in patients who have known medical problems and schedule for stressful dental procedure.
 - *Unknown medical problems*—in some patients abnormalities are detected while history taking or physical examination or laboratory studies. Patient is unaware of this problem.

- *High risk patient*—some patient have high risk for development of particular problems. For example, obese patient may have hypertension.
- *Additional information*—in patient who require additional information which may alter dental care and assist in the diagnosis of orofacial problems.

Consultation letter

Place

Date

Patient Name

Referral doctor name

To

Dr X

I am referring the patient ——— who has to undergo stressful procedure. We have to use local anesthesia for this patient. Medical history of patient reveals that he is suffering from ———. Please advice us about the status of the patient whether he can undergo stressful dental procedure, which type of local anesthesia should we use and what precaution should we take.

Patient signature

Date

Doctor signature

Date

Please return this consultation to

- *Medical questionnaire*—one should ask the following particulars to the patient.
 - *Systemic problems*—whether the patient was suffering from any medical problems before? If yes, what was the duration and treatment? Whether the treatment was beneficial or not? Whether he had taken any medication for that? Patient must be reminded that medicine may include anything taken into the body that is not food. All diseases suffered, by the patient, previous to the present one should be recorded. These diseases may not have any relation with present disease; particular attention must be given to diseases like diabetes, asthma, bleeding disorders, hypertension, myocardial infarction, hepatitis B, diphtheria, rheumatoid heart disease, tuberculosis, and gonorrhea.
 - *Chest pain*—history of chest pain should be asked. As we will come to know the cardiological status of the patient.
 - *Allergy*—whether he has any allergy? (According to that the treatment plan may be adjusted). Allergy can be due to any drug or food. Patient should be asked

about asthma, eczema and hay fever, urticaria, angioedema etc.

- *Previous hospitalization*—ask the patient to enumerate all previous hospitalizations and indicate the purpose.
- *Blood transfusion*—history of blood transfusion should be asked.
- *Accident and operation*—Previous operations, fractures, and accidents should also be noted.
- *Drug history*—you should ask patient to tell the medication that they are presently taking.

Personal History (Fig. 7-7)

- *Habits and addiction*—it is important aspect of history taking. There are many diseases which can correlate with particular habit of the patient. The most important habit you should ask about the tobacco, smoking and alcohol. You should note down frequency per day and length of time that patient had habit in years.
- *Oral hygiene and brushing technique*—bad oral hygiene and improper brushing technique may lead to dental caries and periodontal disease. Horizontal brushing technique may lead to cervical abrasion of the teeth.
- *Pressure habits*—thumb sucking, lip sucking, and finger sucking may lead to anterior proclination of maxillary anterior teeth.
- *Tongue thrusting*—it may lead to anterior and posterior open bite and proclination of anterior teeth.
- *Mouth breathing*—it may lead to anterior marginal gingivitis and caries (Fig. 7-5).

Fig. 7-5: Mouth breathing habit may lead to gingivitis (Courtesy Dr Abhishek Soni).

- *Bobby pin opening*—seen in teenage girls who open bobby pin with anterior incisors to place them in the hair. This results in notching of incisors and denudation of labial enamel.
- *Other habits*—nail biting, pencil and lip biting (Fig. 7-6), lead to proclination of upper anterior and retroclination of lower anterior teeth.

- *Bruxism*—it may lead to attrition.
- *Tobacco*—tobacco preparations such as khaini, manipuri tobacco, mawa, mishri, pan, snuff, zarda etc should be ask.
- *Smoking*—smoking habits such as bidi, chutta, cigarette, dhumti, hookah, etc.
- *Drinking habit*—drinking alcohol, charas, ganja, marijuana etc.

Fig. 7-6: Lip biting habit of patient (Courtesy Dr Shetty).

- *Patient's appetite*—whether it is regular or irregular? You should ask the type of diet (vegetarian, mixed, spicy food) to the patient.
- *Soft diet*—soft refined diet adheres tenaciously to the teeth and is not removed because of lack of rough edges leading to more dental caries than coarse diet.
- *Coarse diet*—in persons, having coarse diet, there is more evidence of attrition.
- *Carbohydrate content*—increased carbohydrate contents leads to increased prevalence of dental caries. Phosphate diet prevents dental caries.
- *Vitamin deficiency diet*—diet having deficiency of vitamins may cause enamel hypoplasia. Deficiency of calcium and phosphorus during period of tooth formation results in enamel hypoplasia and defects of dentin. Vitamin D can reduce the caries incidence.
- *Fluoride content*—fluoride content may influence the caries process.
- *Bowel and micturition habit*—Is it regular or irregular?
- *Sleep*—insomnia occurs in cases of primary thyrotoxicosis.
- *Social status*—caries, arteriosclerosis, heart disease, and acute appendicitis are more common in middle and high

Fig. 7-7: Diagrammatic representation of personal history.

social status individual. Periodontitis, tuberculosis, anemia due to malnourishment is more common in low social status individual.

- **Menstrual and obstetric history**—you should ask about premenstrual tension, presence or absence of pain with periods, whether the patient is taking oral contraceptives, obstetric history, miscarriage, therapeutic abortion. Excessive bleeding may occur during childbirth in cases of hematological disorders. Endocrine diseases may be accompanied by abnormalities of pregnancy, labor and lactation. Cardiac failure may be triggered by circulatory demand of pregnancy and labor.
- **Domestic and marital relationship**—ascertain feelings about other members of family. Interest, hobbies, hopes, fears, the amount of exercise taken. Interest in games and sports. In males, particularly, if unmarried consider the possibility of homosexuality which may be associated with personal and social stresses that may culminate in mental illness.
- **Home surrounding**—whether the surrounding is overcrowded or there is loneliness? What pets are kept?
- **Travel abroad**—whether the patient has lived abroad and if so whether he/she was ill there? Recent travel- e.g., patient may suffer from malaria if he has recently traveled from or even through malaria prone area.

- **Masochistic habit**—some children use the finger nail to strip away the gingival tissue from the labial surface of a lower cuspid. If not discontinued, the marginal and attached gingival tissue will be stripped away exposing the alveolar bone.

Family History

This is very important for many hereditary diseases. Many diseases recur in families like hemophilia, diabetes mellitus, hypertension and heart diseases.

Other Past History

- **Past laboratory investigations**—this will aid in diagnosis of the disease.
- **Previous hospitalizations and operations**—this is important as it can affect the treatment plan of the patient.
- **History of immunization**—you should ask history of immunization regarding chickenpox, mumps and measles. The reason behind this is that, many oral manifestations may mimic above disease.
- **History of allergy**—this is very important. You should ask history of allergy to the drug, specific allergen or any other specific allergy.

Examination

Steps of Clinical Examination

- **Inspection**—it is referred to as passive visualization of the lesion. Intraorally mirror can be used for visualization of structure.
- **Palpation**—this will help for evaluation of structure and to know their consistency, fixity etc.
 - **Bilateral palpation**—this is done to differentiate between symmetrical structures on both side of face (Fig. 7-8).
 - **Bidigital palpation**—in this, two fingers are used to manipulate the tissue. It is used for thinner structure (Fig. 7-9).
 - **Bimanual palpation**—it is done by palms of both hands. In this, one hand is used to support the structure hand and another is used to manipulated the structure. This type of palpation is used in floor of mouth (Fig. 7-10).
- **Auscultation**—it is used to study the movement of TMJ and also used for examination of venous malformation (Fig. 7-11).
- **Probing**—this is used to detect carious lesion.
- **Percussion**—this is used to check whether patient is having periapical infection.

Fig. 7-8: Bilateral palpation is done to palpate the TMJ.

Fig. 7-9: Bidigital palpation is done in case of thinner structure.

Fig. 7-10: Bimanual palpation done in case of floor of mouth.

Fig. 7-11: Auscultation of TMJ is done to examine the movement of TMJ.

General Examination

Build

It can be described as poorly built, moderately built and well built.

- *Asthenic*—it appears as lean and underweight.
- *Sthenic*—they are athletic in appearance.
- *Hypersthenic*—persons have thick muscular and heavy bone structure.
- *Pyknic*—they appear as heavy and rounded.
- *Cachexia*—there is abnormally low tissue mass, occur due to malnutrition.

Pulse

- *Significance*—it is an important index for severity of illness, abnormalities of heart and the vascular system e.g. hypertension and hypotension, shock, fever and thyrotoxicosis.
- *Types of pulse*—pulse can be radial pulse (located on ventral aspect of wrist), branchial pulse (located medial to biceps tendon in the antecubital fossa) and carotid pulse (medial to sternocleidomastoid muscle, inferior and medial to the angle of mandible).
- *Technique*—Assuming that the radial pulse is to be examined, the examiner should take the opportunity to note the warmth of the hand. Find the radial artery a few centimeters proximal to the wrist and just medial to the radius. Palpate the artery wall with the tips of the index and middle fingers. The tips are very sensitive. Avoid the thumb for fear of misinterpreting your own radial pulse. Do not press too hard for fear of obliterating the pulse (Fig. 7-12).

Fig. 7-12: Palpation of radial artery for the examination of pulse of the patient.

- *Points to be noted*—following are particularly noted in pulse:
 - *Rate*—fast or slow (normal 60-100 beats/min).
 - *Rhythm*—regular or irregular, irregularly irregular in arterial fibrillation and regularly irregular in ventricular ectopic.
 - *Volume*—high, low and normal volume indicate pulse pressure (normal pulse pressure is 40-60 mm/Hg). Narrow pulse pressure is in left ventricular failure, obstruction to left ventricle like mitral stenosis, aortic stenosis. Wide pulse pressure in aortic and mitral regurgitation, high output states like pregnancy, anemia etc.
 - *Tension and force*—it indicates diastolic and systolic pressures.
 - *Character*—water hammer pulse of aortic regurgitation, *pulsus paradoxus* of pericardial effusion, *anaerotic pulse* (it is a slow rising twice beating pulse where both waves are felt during systole in carotid artery) in aortic stenosis, *pulsus bisferingus* (it is a rapid rising twice beating pulse where both waves are felt during systole) in idiopathic hypertrophied subaortic stenosis, *dicotic pulse* (it is twice beating pulse where the first percussion wave is felt during systole and second dicotic is felt during diastole) in fever like typhoid, congestive cardiac failure, cardiac tamponade following open heart surgery.
 - *Other factors*—other factors like condition of arterial wall, peripheral pulsations of radial artery, carotid artery, brachial artery should also be seen. Delay of the left temporal pulse compared with right pulse is found in coarctation of aorta.

Blood Pressure

- *Normal blood pressure*—Systolic 120–140 mm Hg and diastolic 80 mm Hg (any above 90 is abnormal). Normal—

120/80 mm Hg. The stroke volume of the heart and stiffness of the arterial vessels control systolic blood pressure. Peripheral resistance controls diastolic blood pressure.

- *Blood pressure variation*—blood pressure varies with emotion, exercise, meal, alcohol, tobacco, bladder distension, temperature and pain.
- *Conditions diagnosed by blood pressure*—conditions diagnosed by blood pressure are hypertension, hypotension and aortic incompetence.
- *Unequal blood pressure*—unequal blood pressure in 2 arms may be due to supravalvular aortic stenosis (right side higher blood pressure), preductal coarctation of aorta (same) and unilateral occlusive disease of aorta.
- *Procedure for blood pressure determination*—blood pressure determination is easily accomplished and is well within the capabilities of every dentist. The procedure is as follows.
 - *Equipment*—the equipment required is stethoscope and sphygmomanometer.
 - *Patient position*—seat the patient and place his right arm on a table or desk so that the forearm is adequately supported at elbow level about the level of heart.
 - *Placement of cuff*—center the rubber balloon of the cuff over the brachial artery (**Fig. 7-13**). The artery is usually palpable about three quarters of the way across the arm going in a lateral to medial direction. Wrap the pressure cuff smoothly and snugly around the upper arm with its lower border 1 to 2 inches above the elbow crease in the antecubital fossa.

Fig. 7-13: Measurement of blood pressure with the help of stethoscope and sphygmomanometer.

- *Pumping of cuff*—palpate the patient's radial pulse and pump the cuff up to above 20 to 30 mm Hg, the point at which the pulse is no longer palpable. It is essential to always record the systolic pressure by palpation to avoid missing the occasional occurrence of silent gap in hypertensive patients.

- *Measurement of systolic pressure*—applies either the bell or the diaphragm of the stethoscope over the artery just distal to the elbow crease and slowly deflates the cuff about 3 mm Hg per heart beat until the first sound appears. Record this first sound as a systolic pressure.
- *Measurement of diastolic pressure*—further lower the pressure in the cuff until the sound disappears. Record this point as the diastolic pressure.
- *Errors*—faulty technique in taking the blood pressure may induce error. If the cuff is applied too loosely and if it is not completely deflated before applying or it is too small for the patient's arm size, the pressure reading obtained will be inaccurately high and will not represent the pressure in the artery at the time of determination. Anxiety and pain are factors that may cause an elevation of the blood pressure of the patient above his true resting level.

Temperature

- *Procedure*—this is normally taken in the mouth or in the axilla by keeping mercury thermometer (**Fig. 7-14**) for a minute. The temperature of mouth is about 1 degree higher than that of axilla. The normal body temperature varies from 36 degree Celsius to 37.5 degree Celsius. The lowest temperature being between 2-4 am and highest in the afternoon. The normal oral temperature is 37°C. Fever or pyrexia is more than 1 degree or any rise above the maximum normal temperature.
- *Conversion of Fahrenheit to Celsius*—temperatures usually taken in Fahrenheit and to convert Fahrenheit into Celsius subtract 32 and multiply by 5/9.

Fig. 7-14: Temperature should be recorded with the help of thermometer.

- *Types of fever*
 - *Continuous fever*—the temperature remains above normal throughout the day and does not fluctuate more than 1 degree in 24 hours. E.g. lobar pneumonia, typhoid and infective endocarditis.
 - *Remittent fever*—The temperature remains above normal throughout the day and fluctuates more than 1 degree in 24 hours e.g. typhoid.
 - *Intermittent fever*—the temperature is present only for some hours in a day and remits to normal for the remaining hours. When the spike occurs daily, it is called as 'quotidian', when every alternate day it is

'tertian', and when every 3rd day it is 'quartian' e.g. malaria, kala azar, pyemia and septicemia.

- *Septic fever*—the temperature variation between peak and nadir is very large and exceeds 5 degrees e.g. in septicemia.
- *Low grade fever*—temperature is present daily especially in the evening for several days but does not exceed 37.8 degree at any time, like in tuberculosis.
- *Hyperpyrexia*—tetanus, malaria, septicemia, heat stroke, encephalitis, and hemorrhage.
- *Benefit of fever*—in some diseases, fever is beneficial. Fever is associated with release of endogenous pyrogen, which activates T cells and thus enhances the host defense mechanism.
- *Harmful effects*—there is hypercatabolism—N₂ wastage and weight loss, fluid and electrolyte imbalance due to sweating, convulsions, brain damage, circulatory overload and arrhythmias.
- *Hypothermia*—hypothermia may be caused by endocrine disorders like hypothyroidism, hypopituitarism hypoglycemia, toxicity like alcohol intoxication, barbiturate poisoning, ketoacidosis, and exposure to cold and autonomic dysfunction.

Respiration

- *Significance*—it is used to assess the condition of the patient under anesthesia and in early postoperative days.
- *Procedure*—you should always check the respiration while checking the pulse of the patient. You should look at the patient abdomen and see how many times he breath. One complete cycle of inspiration and expiration is counted as one. Normal rate—14-18 cycles/minute (**Fig. 7-15**).
- *Tachypnoea* (fast breathing)—it occurs in fever, shock, hypoxia, cerebral disturbances, metabolic acidosis, tetany, and hysteria.

Fig. 7-15: Respiration rate of the patient should be counted while examining the pulse of the patient by looking at the abdomen.

- *Bradypnoea*—slow and deep respiration is seen in cerebral compression.
- *Snoring noise*—paralysis of the soft palate causes an inspiratory snoring noise.
- *Expiratory wheezing*—expiratory wheezing is heard in bronchitis and asthma.

Clubbing

- *Definition*—clubbing is bulbous enlargement of soft part of the terminal phalanges of the nail (**Figs 7-16 and 7-17**).

Fig. 7-16: Lateral view of clubbing showing bulbous enlargement of soft part terminal phalanges on nail (Courtesy Dr Milind Chandurkar).

Fig. 7-17: Clubbing seen in nails of leg of patient (Courtesy Dr Milind Chandurkar).

- *Causes*—it includes:
 - *Pulmonary causes*—like bronchogenic carcinoma, lung abscess, bronchiectasis, and tuberculosis with secondary infection.
 - *Cardiac causes*—like infective endocarditis and cyanotic congenital heart disease.
 - *Alimentary causes*—like ulcerative colitis, Crohn's disease and biliary cirrhosis.

- *Endocrine causes*—like myxedema and acromegaly.
- *Miscellaneous causes*—like hereditary, idiopathic and only in upper limb in heroin addicts due to chronic obstructive phlebitis.
- *Pseudoclubbing*—in hyperthyroidism due to excessive bone resorption there is 'drumstick appearance' of the finger resembling clubbing.

Cyanosis

- *Definition*—cyanosis is the bluish discoloration due to increased amount of reduced Hb (more than 5 mg%) in capillary blood.
- *Types*—it can be central, peripheral, cyanosis due to abnormal pigment or mixed.
- *Sites where peripheral cyanosis is looked for*—nailbed, tip of the nose, skin of the palm and toes.
- *Sites where central cyanosis is looked for*—tongue and other sites mentioned above. Tongue is unaffected in peripheral cyanosis.
- *Causes*
 - *Central*—cardiac causes like congenital cyanotic heart disease and congestive cardiac failure, pulmonary causes like chronic obstructive lung disease (**Fig. 7-18**), collapse and fibrosis of lung, pulmonary obstruction, and high altitude due to low pressure of O₂.
 - *Peripheral*—it includes cold, increased viscosity of blood and shock.
 - *Mixed*—it includes acute left ventricular failure, mitral stenosis and cyanosis due to abnormal pigments like sulfonamides and aniline dye.

Fig. 7-18: Central cyanosis seen in tongue showing bluish discoloration of tongue due to chronic obstructive lung disease.

Icterus

- *Definition*—in jaundice, there is icteric tint of the skin, due to presence of bilirubin, which varies from faint

yellow of viral hepatitis to dark olive greenish yellow color of obstructive jaundice.

- *Site where you should look of Icterus*—the places where one should look for Icterus are sclera of the eyeball (**Fig. 7-19**), nailbed, lobule of ear, tip of the nose and under surface of tongue.
- *Hypercarotenemia*—jaundice may be confused with hypercarotenemia in which yellow pigment of carotene is unequally distributed and is particularly seen in the face, palm and soles but not in the sclera. It occurs mostly in vegetarians.

Fig. 7-19: Icterus seen in eyes of patient who is suffering from jaundice (Courtesy Dr Bhaskar Patle).

Extraoral Examination

Skin

- *Appearance*—changes in appearance, rashes, sores, lumps or itching is looked for and history of sun exposure is questioned.
- *Color*—it is seen for anemia and jaundice.
 - *Generalized pallor*—it is seen in severe anemia. Pallor can be seen in hypopituitarism, shock, syncope, left heart failure and Raynaud's disease.
 - *Lemon yellow tint*—a pale lemon yellow tint in hemolytic jaundice and dark yellow or orange tint in obstructive jaundice is seen.
 - *Yellowness of skin*—yellowness of skin is seen in carotenemia.
- *Texture*—it is thickened, greasy and loose in acromegaly. In dehydration, skin is dry and inelastic so that it can be pinched into ridge. Skin is atrophied with age and sometimes after treatment with glucocorticoids.
- *Signs*—such as petechial hemorrhage indicating blood dyscrasias.
- *Eruptions*—any eruption such as macule, papule, vesicle or bulla.
- *Pigmentation*—pigmentation of Addison's disease affects buccal mucous membrane as well as skin in regions subjected to friction. In Von Recklinghausen's disease, milky coffee pigmentation on the limbs, trunk and face.
- *Edema*—in acute nephritis, edema of face is marked when patient rises in the morning. Dependent edema with pallor and glossy appearance over the swollen part, doughy consistency, and pitting on pressure is characteristic.

Head

- *Headache*—important symptoms like headache should be noted. Following point should be noted in headache.
 - *Nature of headache*—persistent or intermittent and localized or generalized. Unilateral or bilateral or frontal. Associated with unusual disturbances. Familial disorder or induced by stress.
 - *Site*—the exact location of headache.
 - *Radiation*—does it stay in its place or does it move or spread?
 - *Severity*—does it interfere with daily activity or keep you awake at night?
 - *Timing and duration*—when did it start, when does it come and when does it go, has it changed since it began?
 - *Character*—shooting or pricking etc.
 - *Occurrence or aggravation*—what brings it on, and what makes it worse.
 - *Relief*—what makes it better?
- *Head circumference*—hydrocephalus should be suspected when the rate of growth of the head is greater than normal for the sex, age and size of the infant.

Jaws

- *Normal landmark*—normal anatomic landmarks to be identified include mandibular border, angle of mandible, condyle and coronoid process, maxillary bone, lingual notch and maxillary sinus.
- *Tenderness over the jaws*—note any tenderness over the joint or masticatory muscles (temporalis, masseter) while palpating externally over lateral pterygoid and buccinator muscles (distal and lateral to upper molar teeth) and medial pterygoid muscle (pterygomandibular ligament and medial aspect of anterior faucial pillars) with the mouth open.
- *Trauma*—any trauma to head and neck such as injury from motor vehicle or bicycle accident, injury to the side of face and chin should be looked for.

Temporomandibular Joint

The clinical examination for a patient with possible temporomandibular disorder supplements the routine regional head and neck examination. Following point should be noted while examining the temporomandibular joint.

- *History*—medical history about illness, particularly rheumatoid arthritis, degenerative joint disease, osteoarthritis should be asked. Before treatment of temporomandibular joint disorder is initiated, it is necessary to exclude other disorders that might present with similar symptoms like trigeminal neuralgia, multiple sclerosis, glossopharyngeal neuralgia, temporal arteritis, migraine headache, angina pectoris, pulpoperiodontal disease, salivary gland inflammation, duct blockage, otitis, sinusitis and psychogenic pain.
- *Symmetry of face*—the symmetry of the face should be assessed. Gross asymmetry reflects growth disturbances.
- *Interincisal opening*—the maximum interincisal opening of the mouth should be determined, which is, normally, in an adult, 35-50 mm. Measurement also should be recorded for the degree of opening where pain begins.
- *Mandibular movement*—any deviation of the mandible during opening should be noted, along with its severity. The lateral mandibular range of motion is determined by having the patient to occlude the teeth and then slide the jaw in both directions. The range of movement from the midline is measured in mm and any pain along with location and severity is recorded. Normal lateral movement is usually 8-10 mm.
- *Question to be asked to patient*—jaw and joint symptoms should also be discussed with the patient:
 - Does the TMJ click or pop on opening or closing?
 - Has there been limitation in the movement or deviation of the lower jaw on opening?
 - Has the jaw ever locked or dislocated on opening?
 - Has the patient experienced pain and dysfunction in other joints of the body?
- *Palpation of joint*—palpate the joint and listen for clicking and crepitus during the opening and closing of the jaw. Use stethoscope to characterize and locate this sound accurately. Explore the anterior wall of external auditory meatus for tenderness and pain that are usually associated with arthritic changes.
- *Methods of palpation*
 - *Pretragus palpation*—the patient should be requested to slowly open and close the mouth while the doctor bilaterally palpates the pretragus depression with his/her index fingers (**Fig. 7-20**).
 - *Intra-auricular palpation*—it is also performed by inserting the small finger into the ear canal and pressing anteriorly (**Fig. 7-21**).

Fig. 7-20: Examination of TMJ with pretragus palpation method.

Fig. 7-21: Intraarticular palpation method showing finger inserted in the articular area.

- *Significance of palpation*—it is important to perceive, during the pretragus and intra-auricular palpation, whether the condyle moves symmetrically, with the rotation and translation phase being evident. Palpation is also used to detect the tenderness, clicking and crepitus. Subluxation of the joint is also recorded.

Masticatory Muscle

- *Digital palpation*—regional muscles are examined for the tenderness and trigger points using the digital palpation.
- *Masseter muscles*—the masseter muscles are most effectively examined by simultaneously pressing them from inside and outside the mouth in the process of bimanual palpation.
- *Lateral pterygoid muscle*—the lateral pterygoid muscles are evaluated by inserting a finger each behind the maxillary tuberosities, whereas the medial pterygoid is checked by running a finger in an anteroposterior

direction along the medial aspect of the mandible in the floor of mouth.

Lymph Nodes

- **Significance**—normal lymph nodes are difficult to palpate. Nodes draining area of active infection are usually tender; the overlying skin may be warm and red. Gradually enlarging group of nodes in the absence of local infection and inflammation is a significant finding that suggests either systemic disease (infectious mononucleosis, generalized lymphadenopathy associated with HIV infection, lymphoma) and justifies examination for lymphoid enlargement at distant sites such as axilla, inguinal region and spleen to confirm the generalized nature of the process.
- **Inspection of lymph node swelling**
 - **Position**—position is important, as it will not only give an idea as to which group of lymph nodes is affected but also help in diagnosis.
 - **Number**—it is important since in some diseases there is generalized involvement of the lymph nodes like Hodgkin's disease, lymphatic leukemia and lymphosarcoma.
 - **Pressure effect**—swelling and venous engorgement of the face and neck may occur due to pressure effect of the lymph nodes at the root of the neck.
- **Palpation**—the swelling is palpated for number, situation, local temperature, surface, margin and consistency. Enlarged lymph nodes should be carefully palpated with palmar aspect of the fingers. While rolling the finger against the swelling slight pressure is maintained to know the actual consistency.
- **Fixity to underlying tissues**—the lymph nodes of the neck should be examined by standing behind the patient with the patient's neck slightly flexed.

Fig. 7-22: Palpation of submental lymph node is done by standing in front of the patient and patient neck flexed.

- **Palpation of superficial lymph nodes**—palpation of the lymph nodes of the neck is commonly begun with most superior nodes and worked down the clavicle for supraclavicular nodes, anterior to the tragus of ear for preauricular nodes, mastoid and base of skull for posterior auricular and occipital nodes, under the chin for submental nodes (Fig. 7-22) and further posteriorly for submandibular and sublingual lymph nodes.
- **Examination of deep cervical nodes**—to examine the deep cervical nodes ask the patient to sit erect and turn the head to one side to relax the sternomastoid muscle (Fig. 7-23). Use thumb and finger to palpate under the anterior and posterior borders of the relaxed muscle and repeat the procedure on the opposite side. Palpate the posterior cervical nodes in the posterior triangle close to the anterior border of the trapezius muscle. Finally, check for supraclavicular nodes just above the clavicle, lateral to the attachment of the sternomastoid.

Fig. 7-23: Examination of deep cervical lymph nodes is done by relaxing the sternomastoid muscle.

- **Causes of lymph nodes enlargement**
 - **Inflammatory**—acute lymphadenitis, chronic lymphadenitis, septic, tuberculosis, syphilis, filariasis, and lymphogranuloma inguinale.
 - **Neoplastic**—primary (lymphosarcoma), secondary (carcinoma, sarcoma, malignant melanoma).
 - **Hematological**—Hodgkin's disease, non-Hodgkin lymphoma, chronic lymphatic leukemia.
 - **Immunological**—AIDS, serum sickness, drug reaction, SLE and rheumatoid arthritis.

Examination of Other Parts

- **Nose**—severe nasal obstruction leads to breathing through mouth which leads to dryness of mouth which results in persistent sore throat. Infection from nose may spread to the orbit from the adjacent paranasal sinus. Longstanding nasal obstruction suggests a deviated nasal septum. *Epistaxis* (nasal bleeding) may indicate life threatening conditions like cerebral hemorrhage. Nasal discharge may be purulent, bloody, watery or mucoid.
- **Paranasal sinus**—an apical tooth abscess of the upper jaw may drain into the maxillary sinus causing acute sinusitis.
- **Eyes**—visual disturbances, color of the sclera and conjunctivae are looked for anemia and liver diseases. Ocular pain, diplopia and edema of eyelid etc. are also looked for.
- **Ears**—impaired hearing, loss of hearing, discharge from ears, tinnitus.
- **Neck**—check for movement in neck, lump in the neck, cervical lymphadenopathy. If thyroid enlargement is suspected, check if the mass moves up and down with trachea when the patient swallows.
- **External jugular vein**—observe the external jugular vein as it crosses the sternomastoid muscle and with the patient at an angle, approximately 45 degree to the horizontal, note any distension and/or pulsation in the vein. Distension more than 2 cm above the sternal notch is abnormal and is seen in severe right side heart failure.

Intraoral Examination

Intraoral examination is the most important part in dental point of view.

Diagnostic Set of Instrument

Basic diagnostic set which require for intraoral examination are mouth mirror, tweezers, probe, explorer. The use of mirror is mainly for the retraction and indirect vision. Never

Fig. 7-24: Basic diagnostic set of instrument consist of mouth mirror, probe, tweezers, explorer.

try to directly visualize upper teeth in the patient mouth (Fig. 7-24).

Doctor's Position

Position of doctors is very important while intraoral examination. As there are many professional hazards which occur due to improper position of the doctors.

- **Basic position**—doctor should be either low seated or in standing position. In cases of examining while doctors in standing position, he should stand erect without bending of spinal cord. Patient head should be at elbow level of the doctor. The ideal position is 10 o' clock or 11 o' clock position.
- **Guideline for examination**—you should avoid resting arms over patient shoulder, and maintain comfortable distance from the patient. Eye contact should be maintained with the patient. Drape the patient and avoid keeping instrument on the patient chest.
- **Upper left posterior region**—In this case doctors should stand behind the patient with his left hand going around the patient head (Fig. 7-25).

Fig. 7-25: Doctor's position of upper left posterior region.

- **Upper right posterior region**—doctors should stand at side of patient (Fig. 7-26).
- **Lower right posterior region**—in this case, doctors should stand at side of the patient (Fig. 7-27).
- **Lower left posterior region**—in this case, doctor should stand behind the patient (Fig. 7-28).

Examination of Nondental Structures

Tongue

Inspection

- **The volume of the tongue**—massive tongue due to lymphangioma, hemangioma and neurofibroma.

Fig. 7-26: Doctor's position for upper right posterior region.

Fig. 7-27: Doctor's position for lower right posterior region.

Fig. 7-28: Doctor's position for lower left posterior region.

- *Papillae of tongue*—observe and note the distribution of filiform and fungiform papillae, margins of the tongue, crenation and fasciculation, depapillated areas, fissures, ulcers and keratotic areas.
- *Color*—the white color of leukoplakia, candidiasis (Fig. 7-29) the red color tongue when the leukoplakic plaque gets desquamated, blue color of venous hemangioma. Black hairy tongue due to hyperkeratosis of the mucous membrane in heavy smoker or caused by fungus aspergillus are very characteristic. In jaundice, yellowish tint to the tongue may be seen.

Fig. 7-29: One should note the color of tongue. In this case, color is white due to candidiasis

- *Any crack or fissure*—note the direction of fissure; congenital fissures are mainly transverse whereas syphilitic fissures are usually longitudinal.
- *Swelling and ulcer*—examine the tongue for any swelling or ulcer. If there is a swelling or an ulcer, note the size, shape, extent, margin etc. Also note whether it has extended to the floor of mouth, to the jaw or tonsil. The site of the ulcer is usually characteristic; like the dental ulcer appears on the side of the tongue where it comes in contact with sharp teeth or dentures, tuberculous ulcer on the lip and side of tongue, gummatous ulcer on the dorsum and carcinomatous ulcer occurs usually on the margin of the tongue.
- *Mobility of the tongue*—ask the patient to put the tongue out and move it side ways (Fig. 7-30). Inability to put the tongue out completely is due to ankyloglossia. If the tongue deviates to one side during the protrusion it indicates impairment of nerve supply to that half of the tongue. This is noticed in carcinoma of the tongue, which has damaged the nerve supply of consequent side. If the child with impaired speech fails to protrude the tongue, it is possibly due to tongue-tie; look for short frenum linguae.

Fig. 7-30: Mobility of tongue can be checked by holding it with the hand.

- *Tongue thrusting*—note tongue thrust on swallowing.
- *Central cyanosis*—look for central cyanosis.

Palpation

- *Procedure*—while palpating for induration of the base of an ulcer, tongue should be relaxed and at rest within the mouth. If it is kept protruded, the contracted muscles may give a false impression to induration and lead to error in diagnosis. Induration is an important clinical sign of epithelioma. It may be present in gummatous ulcer but is absent in tubercular ulcer.
- *Points to be noted*—note whether ulcer bleeds during palpation. This usually occurs in malignant ulcer. Palpate carefully for a sharp tooth or tooth placed against an ulcer in the tongue. Palpate the back of the tongue for any ulcer or swelling.

Palate

Inspection

- *Point to look for*—congenital cleft, perforation, ulceration, swelling, fistulae, papillary hyperplasia, tori, recent burns and hyperkeratinization.
- *Cleft examination*—in case of congenital cleft, note the extent of the cleft (involving only the uvula, only the soft palate or part or whole of the hard palate). Whether the nasal septum is hanging free or attached to one side of the cleft (**Fig. 7-31**).
- *Perforation*—perforation of the hard palate is usually caused by gumma.
- *Scar of operation*—any scar of the operation around or history of operation, as sometime a hole may persist after an operation for closure of congenital cleft.

Palpation

- *Point to look for*—tender, fluctuating swelling close to alveolar process is an alveolar abscess. Soft swelling in the midline of the hard palate is gumma.

Fig. 7-31: Note for any cleft in the palate while examining. In this case, cleft is due to cleft palate.

Lip

Inspection

- *Point to be noted*—note lip color, texture and any surface abnormalities, angular or vertical fissures.
- *Cleft*—cleft lip (**Fig. 7-32**), either complete or incomplete, bilateral complete cleft lip in which there is also cleft palate and protuberant pre-maxilla. Cleft between maxilla and side of the nose.
- *Pigmentation*—pigmentation of lip and buccal mucosa in Addison's disease. In Peutz Jeghers syndrome, melanin pigmentation of the lip and oral mucosa occurs.
- *Chancre*—chancre on lip is a painless ulcer with dull red color.
- *Ectopic salivary neoplasm*—ectopic salivary neoplasm is seen in upper lip as slow growing, lobulated tumor.
- *Macrochelia*—thickening of the lip which often involves the upper lip.
- *Cheilitis*—in cheilitis glandularis, lower lip becomes enlarged, firm and everted. In cheilitis granulomatosa, there is diffuse swelling of the lower lip.

Fig. 7-32: Cleft lip should be properly examined in patient.

Palpation

- *Point to be noted*—benign neoplasm is firm and lobulated while carcinoma of the lip is hard in consistency. Chancre is rubbery hard whereas carcinoma is stony hard. Mucous retention cyst is seen on the inner surface of the lip. In cheilitis granulomatosa, the swelling is soft usually exhibiting no pitting on pressure.

Floor of Mouth**Inspection**

- *Procedure*—ask the patient to open his mouth and to keep the tip of tongue upward to touch the palate. This will expose the floor of mouth.
- *Point to be noted*—any swelling, red-white patches in the floor of mouth should be noted.
- *Color of swelling*—when a swelling is present note its color. A ranula appears as a unilateral bluish translucent cyst over which Wharton's duct can be seen. In hemangioma swelling is red in color (**Fig. 7-33**).
- *Site of lesion*—a sublingual dermoid lies exactly in the midline and may extend into the submental region. A deeper plunging ranula may have cervical prolongation into the submandibular region.
- *Ankyloglossia*—in ankyloglossia there is fusion between the tongue and floor of mouth.

Fig. 7-33: Swelling in floor of mouth is due to hemangioma.

Palpation

- *Point to be noted*—Ranula is a fluctuant swelling with positive translucence. Sublingual dermoid which is not translucent but tense and fluctuant swelling is seen on the midline. Carcinoma of the floor of mouth is revealed by its indurated base and probable fixation to the underlying structures.

Cheek**Inspection**

- *Point to be noted*—examine the inside of the cheek for aphthous ulcer, leukoplakia (**Fig. 7-34**), and mucous cyst,

lipoma, mixed salivary tumor, papilloma and carcinoma.

- *Pigmented patches*—pigmented patches are seen in Addison's disease and in Peutz Jegher's syndrome.
- *White lesion*—it can be seen in pronounced linea alba, leukoedema, hyperkeratotic patches.
- *Red lesion*—it can be present in ulcer, nodule, scar, and malignancy.

Fig. 7-34: White patch seen on cheek mucosa due to leukoplakia

Palpation

- *Point to be noted*—mucous cysts have smooth surface and are movable over the deeper structures. Fluctuation can be elicited by pressing on the top of the cyst while the sides are palpated by other 2 fingers. Papilloma is a solid tumor with irregular surface and is mobile over the deeper structures. Carcinoma is fixed and indurated. Palpate the muscles of cheek.

Tonsil and Pharynx

- *Point to be noted*—note the color, size and surface abnormalities of the tonsil. Palpate tonsil for discharge and tenderness. Note restriction of oropharyngeal airway. Observe the faucial pillars for nodules, red and white patches (**Fig. 7-35**), lymphoid aggregates and deformities. Observe the postpharyngeal wall for swelling, nodules, lymphoid hyperplasia, hyperplastic adenoid, and postnasal discharge.

Salivary Glands—Parotid Gland**Inspection and palpation**

- *Swelling*—keep in mind the position of the parotid gland, which is below, behind and slightly in front of the lobule of the ear. A swelling of the parotid gland thus obliterates

Fig. 7-35: Redness in tonsillar area should be noted.

the normal hollow just below the lobule of the ear. Position is important since many of the lymph node swellings are mistaken for parotid gland tumor and vice versa. Note the extent, size, shape and consistency. Whether the swelling is fixed to the masseter muscle or not, is confirmed by asking the patient to clench his teeth and mobility is tested over the contracted masseter muscle.

- *Skin over the parotid gland*—in case of parotid abscess, the skin becomes edematous with pitting on pressure. Fluctuation is a very late feature of parotid abscess as there is strong parotid fascia over the parotid gland. The skin is warm and tender. Any scar or fistula should be looked for. If there is malignancy check if there is infiltration of the skin by the tumor.
- *Duct*—Stensen's duct on the buccal surface of the cheek is opposite to the crown of the upper second molar

Fig. 7-36: Stensen's duct opening seen in upper second molar region as a papilla.

(Fig. 7-36). For its proper inspection, retract the cheek with spatula. If there is suppurative parotitis gentle pressure over the gland will cause purulent saliva to come out of the orifice of the duct. Blood will come out in case of malignant growth of the gland. The terminal part of the duct is best palpated bidigitally between the index finger inside the mouth and the thumb over the cheek.

- *Fistula*—if there is parotid fistula, note its position and whether it is in relation to the gland or duct.
- *Examination of facial nerve*—facial nerve is not involved in benign tumor but is involved in malignant growth.
- *Lymph nodes*—preauricular, parotid and submandibular groups of lymph nodes are mostly involved.
- *Movement of the jaw*—it may become restricted if the growth is malignant and has involved the pre-articular tissue of TMJ.

Submandibular Salivary Gland

- *History*—swelling with colicky pain at the time of meals suggests obstruction in submandibular duct. It is tense and painful. Swelling is more often due to lymph node enlargement rather than salivary gland enlargement. If the patient gives the history which is suggestive of a stone in the duct ask the patient to suck a little lemon or lime juice. The swelling will appear at once.
- *Mikulicz's disease*—in Mikulicz's disease; submandibular, parotid as well as lacrimal glands are enlarged.
- *Wharton's duct*—inspection of the Wharton's duct is made by means of torch on the floor of mouth which is situated on either side of lingual frenum. Whether the orifice is inflamed or swollen? If the gland is infected, slight pressure on the gland will exude pus through the respective orifice. If stone is suspected in one duct, saliva will be seen coming out with normal flow from the other orifice while the affected duct orifice remains dry. This is tested by putting dry sweets one on each orifice and some lemon juice is given on the dorsum of the tongue, 2 minutes later the sweets are taken out. The sweet on the orifice of the duct where the stone is suspected will remain dry.
- *Bimanual palpation*—patient is asked to open the mouth; one finger of one hand is placed on the floor of mouth medial to the alveolus and lateral to the tongue and pressed on the floor of mouth as far as possible. The finger of the other hand on the exterior are placed just medial to the inferior margin of the mandible. These fingers are pushed upward; this will help to palpate both the superficial and deep lobes of submandibular salivary gland. This also differentiates an enlarged salivary gland from enlarged submandibular lymph nodes.

Mucobuccal Fold

- *Point to be noted*—observe color, texture, any swelling, and fistulae. Palpate the swelling and tenderness over roots of the teeth and look for tenderness of the buccinator insertion by pressing laterally with finger over roots of the upper molar teeth.

Examination of Dental Structures

Teeth

- *Teeth nomenclature*—various nomenclature systems used are as follows
 - *Zsingingdy's and palmar method*—it is the oldest method of recording teeth. The oral cavity is divided into four quadrants. For deciduous teeth and permanent teeth dental formula is as follows

Deciduous teeth	Permanent teeth
EDCBA ABCDE	87654321 12345678
EDCBA ABCDE	87654321 12345678

- *Universal system*—the primary teeth in the maxillary arch are designated by letter A through J, beginning with the right second molar. The teeth in mandibular arch are designated by letter K through T beginning from the left second molar. Similarly for the permanent teeth numbers 1 to 32 are used.

Permanent teeth—

1 2 3 4 5 6 7 8	9 10 11 12 13 14 15 16
32 31 30 29 28 27 26 25	24 23 22 21 20 19 18 17

Deciduous teeth—

A B C D E	F G H I J
T S R Q P	O N M L K

- *F.D.I (two digit system)*—in it first digit indicates the quadrant as 1 to 4 of the permanent teeth and 5-8 for primary teeth. The second digit indicates the tooth in the quadrant. Thus, deciduous upper right second molar is denoted as 55 and pronounced as five-five and not fifty five and first mandibular left permanent molar is denoted as 36.

Permanent teeth—

18 17 16 15 14 13 12 11	21 22 23 24 25 26 27 28
48 47 46 45 44 43 42 41	31 32 33 34 35 36 37 38

Deciduous teeth—

55 54 53 52 51	61 62 63 64 65
85 84 83 82 81	71 72 73 74 75

- *Dane system*

Permanent teeth—

+8+7+6+5+4+3+2+1	+1+2+3+4+5+6+7+8
-8 -7-6-5 -4-3-2 -1	-1-2 -3-4 -5-6-7-8

Deciduous teeth—

+05+04+03+02+01	+01+02+03+04+05
-05-04 -03-02 -01	-01 -02-03-04-05

- *Point to look for*—you should look for caries (pit and fissure, smooth surface caries, cervical caries), defective restoration or recurrent caries. You should also note missing and supernumerary teeth (Mesiodens, paramolar, distomolar). Presence of root piece of badly carious fractured teeth. You should also look for over-retained deciduous teeth, impacted teeth, ankylosed teeth, fusion of teeth, Talon's cusp, dens evaginatus, taurodontism, and anodontia, enamel hypoplasia, mottled enamel, neonatal teeth, eruption sequestra, delay eruption, attrition, abrasion, erosion, sclerosis, pulp calcification, resorption of teeth, hypercementosis, plaque, calculus and stains.
- *Difference between deciduous and permanent teeth*—it is described in **Table 7-8**.
- *Stains and calculus*—stains and calculus should be recorded in the finding. If calculus is present, there are always chance that gingival inflammation is present as calculus act as local irritant. Different grading for stains and calculus is as follows
 - +—stain and calculus involving only cervical portion of teeth (**Fig. 7-37**).
 - ++—stains and calculus extending upto the middle third of teeth (**Fig. 7-38**).
 - +++—stains and calculus involving whole of the facial or lingual surface (**Fig. 7-39**).

Fig. 7-37: Stains showing involvement of cervical portion only.

- *Percussion test*—this test enables to evaluate the status of the periodontium surrounding a tooth. There are two types of percussion tests carried out i.e. vertical percussion and horizontal percussion test.
 - *Vertical percussion test*—if vertical percussion test is positive, it indicates periapical pathology. To carry

Fig. 7-38: Stains ++ showing involvement upto middle third of the patient. In this patient there is also calculus + on the lingual surface.

Fig. 7-39: Stains +++ and calculus ++ in this patient.

out vertical percussion test the tooth is struck a quick, moderate blow, initially with low intensity by the finger and then with increasing intensity by using the handle of an instrument, to determine whether the tooth is tender. First you have to tap adjacent teeth first and then tap an affected one. The patient response should be taken from patient body movement, reflex reaction of eye. If tooth is tender patient will blink his eyes due to pain (**Fig. 7-40**).

- **Horizontal percussion test**—if horizontal test is positive it indicates periodontium associated problems. In case of horizontal percussion test, the procedure is same but direction of blow is in horizontal direction (**Fig. 7-41**).
- **Mobility and depressibility test**—it is used to evaluate the integrity of the attachment apparatus surrounding the tooth.

Fig. 7-40: Vertical percussion test showing tapping of teeth in vertical direction.

Fig. 7-41: Horizontal blow should be given in horizontal percussion test.

- **Mobility test**—the test consists of moving a tooth laterally in its socket by using the finger or preferably in the handles to two instruments. The objective of this test is to determine whether the tooth is firmly or loosely attached to its alveolus.
- **Depressibility test**—similarly, the test for depressibility consist of moving a tooth vertically in its socket. When depressibility test is positive chances of retaining the tooth range from poor to hopeless.
- **Pathologic mobility**—it results from inflammatory process, parafunctional habits or iatrogenic induced situation.
- **Adaptive mobility**—occurs due to anatomic factors such as short roots and /or poor crown to root ratios that are normally directly contributory to mobility.
- **Measurement of tooth mobility**—there are different ways to measure tooth mobility. They are as follows:

Table 7-8: Difference between primary and permanent teeth

Primary teeth	Permanent teeth
The primary teeth are 20 in number	The permanent teeth are 32 in number
The crowns of primary anterior teeth are wider mesiodistally than the cervicoincisally	The cervicoincisal dimension of the permanent teeth are more as compared to mesiodistal dimension
The crown of the primary teeth have prominent cervical ridge on the buccal surface	The buccal surface of the permanent teeth do not have marked cervical ridge as that of the primary teeth
The roots of the primary teeth are narrow and thin	The roots of permanent teeth are more bulky as compared to that of the primary teeth
The crown and roots of the primary teeth show marked cervical constriction	The permanent teeth do not have such as marked cervical constriction
The roots of the primary molar flare out from the cervical third	The roots of the permanent molars do not possess flare as that of the primary teeth
The furcation is close to the cervical line resulting is a short root trunk	The furcation is at a distance from the cervical line resulting in longer root trunk
The primary teeth are lighter in color because of thinner enamel and different refractive index of the enamel	The permanent teeth are yellowish in color because of thicker and more translucent enamel
Both enamel and dentin thickness is less as compared to the permanent teeth	Both enamel and dentin are thicker as compared to the primary teeth
Pulp chambers are larger in size	Pulp chambers are smaller in size
Pulp horns are at higher level	Pulp horns are at a lower level as compared to the primary teeth
Enamel rods are inclined occlusally in the cervical third	Enamel rods are inclined cervically in the cervical third
Number of accessory canals are more	Accessory canals are less in number
Broader and flatter contact areas	Contact areas are less broad

- According to Glickman
 - Grade I—slightly more than normal.
 - Grade II—moderately more than normal.
 - Grade III—severe mobility faciolingually and/or mesiodistally combined with vertical displacement.
- According to Millar—2nd method was developed by Millar (1950) in which tooth is held firmly between 2 instruments and move back and forth and mobility score is noted (Fig. 7-42) as follows
 - 0—it denotes no detectable movement when force is applied other than what is considered normal (physiologic) motion.
 - 1—it indicates mobility greater than normal.
 - 2—mobility up to 1 mm in buccolingual direction.
 - 3—mobility greater than 1 mm in a buccolingual direction combined with the ability to depress the tooth.
- Dental arch irregularities—it classified by Angle as follows
 - Class I—arch in normal mesiodistal relationship, i.e. mesiobuccal cusp of the maxillary first permanent molar occludes in the buccal groove of mandibular first permanent molar (Fig. 7-43). Dewey's modification of class I Angle classification is as follows.
 - Type I—crowded anterior teeth.
 - Type II—proclinated maxillary incisors.
 - Type III—anterior cross bite (Fig. 7-44).
 - Type IV—posterior cross bite.
 - Type V—the permanent molar has drifted mesially due to early extraction of second deciduous molar or second premolar.
 - Class II—mandibular arch distal to normal in its relation to the maxillary arch, i.e. distobuccal cusp of upper first permanent molar occludes in the buccal groove of lower first permanent molar (Fig. 7-45).
 - Div I—proclination of upper incisors, abnormal muscular activity.
 - Div II—lingually inclined upper central incisors and labially tipped upper lateral incisors overlapping the central incisors.
 - Class II subdivision—Class II molar relationship on one side and class I on other side.
 - Class III—mandibular arch mesial to normal in its relation to the maxillary arch, i.e. mesiobuccal cusp

Fig. 7-42: Mobility of tooth is checked by handles of two instruments.

Fig. 7-43: Class I molar relationship showing mesiobuccal cusp of maxillary permanent molar occlude in buccal groove of mandibular first molar.

Fig. 7-44: Anterior cross bite seen in patient (Courtesy Dr Shetty).

Fig. 7-45: Class II molar relationship showing mandibular arch distal to its normal relationship.

of maxillary first permanent molar occluding in interdental space between mandibular first and second molar (**Fig. 7-46**).

- *Class III subdivision*—class III on one side and class I on other side.

Fig. 7-46: Class III malocclusion showing mandibular arch mesial to normal.

- *Occlusion in deciduous dentition*—it is evaluated by following ways
 - *Flush terminal plane*—the distal surface of maxillary and mandibular second molar are in straight plane.
 - *Mesial step*—distal surface of mandibular second molar is more mesial to maxillary second molar.
 - *Distal step*—distal surface of mandibular second molar is more distal to maxillary second molar.
- *Point to look for in dental arch*—orthodontic anomalies, abnormal jaw relationship. Occlusal interference.
- *Presence of periodontal pocket*—it can be true or false pocket. The probe should be inserted parallel to the vertical axis of the tooth and 'walked' circumferentially around each surface of each tooth to detect the areas of deepest penetration (**Fig. 7-47**).
- *Furcation involvement*—the term furcation involvement refers to the invasion of the bifurcation and trifurcation of multirrooted teeth by the periodontal disease. The extent of involvement is determined by exploration with Naber's probe, along with simultaneous blast of warm air to facilitate visualization. There are different grade of furcation involvement which are as follows:
 - *Grade I*—it is incipient bone loss. Clinically only slight catch occurs in furcation area while probing.
 - *Grade II*—partial bone loss. In this case probe can pass in the furcation area upto middle.
 - *Grade III*—total bone loss with through and through opening of the furcation. Probe can pass through and through.
 - *Grade IV*—it is similar to grade III but with gingival recession exposing the furcation to view (**Fig. 7-48A**).

Fig. 7-47: Probe should be inserted parallel to the vertical axis of tooth in periodontal pocket examination.

Fig. 7-48A: Grade IV furcation involvement which is associated with gingival recession.

- **Pulp testing or vitality testing**—there are four types of pulp testing:
 - **Electric pulp testing**—the electric tester, when testing for pulp vitality uses nerve stimulation. The objective is to stimulate pulpal response by subjecting the tooth to an increasing degree of electric current. A positive response is an indication of pulp vitality and helps in determining the normality or abnormality of that pulp. No response to the electrical stimulus can be an indication of pulp necrosis. The procedure is as follows:
 - **Describe test to patient**—describe the test to the patient in a way that will reduce anxiety and will eliminate bias response.
 - **Isolation of teeth**—isolate the area of teeth to be tested with cotton rolls and saliva ejector and air dry all teeth.

- **Apply the electrolyte**—apply an electrolyte (toothpaste) on the tooth electrode, and place it against the dried enamel to the crown's occlusobuccal or incisobuccal surface. It is important to avoid contacting any restoration on the tooth or the adjacent gingival tissue with the electrolyte or the electrode; this will cause a false and misleading response.
- **Retract the patient's cheek**—retract the patient's cheek away from the tooth electrode with the free hand. This hand contact with the patient's cheek completes the electrical circuit.
- **Turn the rheostat**—turn the rheostat slowly to introduce minimal current into the tooth and then slowly increase it and ask the patient to indicate when sensation occurs by using words as "tingling" or 'warmth'. Record the results according to the numeric scale on the pulp tester (**Fig. 7-48B**).

Fig. 7-48B: Electric pulp tester is used for vitality testing of pulp.

- **Thermal testing**—these tests involve the application of cold or heat to a tooth, to determine sensitivity to thermal changes. A response to cold indicates a vital pulp, regardless of whether that pulp is normal or abnormal. An abnormal response to heat usually indicates the presence of a pulpal or periapical disorder requiring endodontic treatment.
- **Heat testing**—the area to be tested is isolated and dried, warm air is directed at the exposed surface of the tooth and the patient's response is noted. If a higher temperature is required then one should use a hot burnisher or hot gutta purcha.
- **Cold testing**—cold air can be directed against the crown of the previously dried tooth and also at the gingival margin. If no reaction occurs the tooth can be isolated under the rubber dam and sprayed with ethyl chloride, which evaporates so rapidly that it absorbs heat and thereby cools the tooth. A more common method is using cotton pellet saturated with

ethyl chloride on the tooth being tested. Another simple method is to wrap a sliver of ice in wet gauze, and to place it against the facial surface of the tooth and to compare to reaction of control tooth.

- **Anesthetic testing**

- *When it is required*—this test is restricted to patient which is in pain at the time of the test, when the usual test has failed to enable one to identify the tooth. The objective is to anesthetize a single tooth at a time until the pain disappears and is localized to specific tooth.
- *Infiltration of teeth*—using either infiltration or the intraligament injection injects the most posterior tooth in the area suspected of being the cause of pain. If pain persists when the tooth has been fully anesthetized, anesthetize the next tooth mesial to it and continue to do so until the pain disappear.
- *Inferior alveolar nerve block*—if the source of the pain cannot be determined, whether in maxillary or mandibular teeth, an inferior alveolar injection should be given.
- *Test cavity*—it is performed when other method of diagnosis have failed. It is made by drilling through the enamel and dentin junction of an un-anesthetized tooth. The drilling should be done at slow speed and without a water coolant. Sensitivity and pain felt by the patient is an indication of pulp vitality. Sedative cement is placed in the cavity and search for the source of infection continues. If no pain is felt, cavity preparation continues until the pulp chamber is reached. If the pulp is completely necrotic, endodontic treatment can be continued in many cases without anesthesia.

Gingiva

- **Color**—normal is coral pink; physiological pigmentation of melanin may be seen.
- **Size**—it corresponds to the sum total of the bulk of cellular and intercellular elements and their vascular supply. Alteration in size is a common feature of gingival disease.
- **Contour**—it depends upon shape of the teeth and their alignment in the arch, location and size of the area of proximal contact and dimension of the facial and lingual gingival embrasures (**Fig. 7-49**).
- **Shape**—it is governed by the contour of proximal tooth surface and the location and shape of gingival embrasures.
- **Consistency**—firm and resilient with exception of free margin.
- **Surface texture**—orange peels appearance or stippled.
- **Position**—the level at which the gingival margin is placed on the tooth.

Fig. 7-49: Irregular shaped contour of gingiva in the patient who has got misalignment of teeth. Gingiva is of normal color.

- **Earliest sign of periodontics**—earliest sign of periodontitis is a deep red line along the free edge of gum. Vincent stomatitis is an inflammatory condition of the gingiva.
- **Cancrum oris**—cancrum oris starts with painful, purple red indurated papule found on the alveolar margin in the region of the molar or premolar teeth which later on ulcerates to rapidly expose the underlying bone and extends to the cheek and lip. Swollen gums, dental abscess and blue line are seen in lead poisoning.
- **Bleeding gums**—as the age advances, there is recession of the gingiva. The gums may bleed, be swollen, spongy and tender in scurvy. Gums may bleed in uremia but may not as spongy as in scurvy. Epulis is the swelling of the alveolar margins of the gums.
- **Gingivitis**—if there is inflammation of the gingiva, it is called as gingivitis. It may be acute or chronic, localized or generalized. Signs of gingivitis are bleeding on slight probing, red, spongy, swollen and edematous gingivae.
- **Periodontitis**—if there is inflammation of the periodontium, that is gingiva, alveolar bone, cementum, and periodontal ligament, it is called as periodontitis. Signs of it include all the sign of gingivitis, gingival recession and alveolar bone loss, foul smell, pocket formation.

Examination of Swelling

Inspection

- **Situation**—a few swellings are peculiar in their position such as dermoid swelling which is mostly seen in the midline of the body or on the line of fusion of the embryonic process. Nasopalatine cyst is common in maxillary anterior region.
- **Color**—the color of swelling should be noted. Color of swelling lead to some clue in the diagnosis.
 - **Black color**—it is of benign nevus and melanoma; red purple color of hemangioma.

- **Pink**—normal color is pink as healthy stratified squamous epithelium is semitransparent and hence, the red color of blood in the extensive capillary bed beneath although somewhat muted shows through. Transitory pink color to whiter appearance is caused due to increased thickness of epithelium layer which occurs due to increased retention of keratin. Masticatory mucosa which is subjected to greatest mechanical stimulation appears light pink, e.g. buccal mucosa, vestibule, floor of mouth and ventral surface of tongue.
- **White**—many pathological variations will impart white color to mucosa. Clinician must be familiar with it.
- **Red**—mucosa changes from pink to red because of thinning of epithelial covering, increased vascularity, and dissolution of part of the collagen content of subepithelial tissue.
- **Yellow**—it is due moderate distribution of adipose tissue contained in connective tissue just beneath the basement membrane e.g. Fordyce's granule.
- **Brownish, bluish or black**—it is induced by melanin, hemosiderin or heavy metal.
- **Contour**—diagnostician must be familiar with normal tissue contour in and around the oral cavity to be able to detect any disorder that might alter the usual configuration of the area (**Fig. 7-50**).

Fig. 7-50: Swelling should be observed for contour, extension, shape.

- **Shape**—the shape of the swelling must be noted, whether it is ovoid, pear or kidney shaped, spherical or irregular. Sometimes, student by mistake utter the term circular to describe the shape of the swelling. A swelling cannot be circular as we do not know about the deeper dimension of the swelling. So it is wiser to say spherical to describe the swelling.

- **Size**—on inspection, we can miss the deeper dimension but we can mention vertical and horizontal extension approximately.
- **Surface**—normal mucosa is smooth and glistening except for area of rugae and attached gingiva which demonstrate stippling and pebbling. Surface of pathological mass may be smooth, ulcerated, papillomatous, eroded, keratinized, necrotic, and bosselated.
 - **Smooth surface**—masses that arise beneath stratified squamous epithelium are *smooth* like fibroma, osteoma, chondroma, hemangioma, intradermal and compound nevus, minor salivary gland tumor, cyst, retention phenomenon, lipoma, schwannoma, neuroblastoma, space abscess and bullous pemphigoid.
 - **Ulcerated surface**—malignant counterparts of above lesions are smooth in early phase but after repeated trauma, they become ulcerated and necrotic.
 - **Cauliflower surface**—it is seen in sq. cell carcinoma, irregular numerous branches on the surface of a papilloma.
 - **Corrugated or papillomatous surface**—masses that originate in the stratified squamous epithelium have 'corrugated' or 'papillomatous' surface like papilloma, verruca vulgaris, seborrheic keratosis, keratoacanthoma, verrucous carcinoma and exophytic growth.
- **Edges**—it may be clearly defined or indistinct, sessile or pedunculated.
- **Skin over swelling**
 - **Red or edematous skin**—it will be red or edematous when the swelling is an inflammatory one.
 - **Tense and glossy skin**—the skin becomes tense, glossy with venous prominence when the swelling is a sarcoma with rapid growth.
 - **Black punctum on skin**—presence of black punctum over a cutaneous swelling indicates sebaceous cyst.
 - **Scar**—presence of scar indicates previous operation, injury or previous suppuration.
 - **Peau d orange skin**—sometimes, the skin over a growth looks like the peel of an orange (peau d'orange), which is due to edematous swelling from blockage of small lymphatics draining the skin.
- **Number**—number of swelling should be noted. Multiple swelling (neuro-fibromatosis), solitary swelling (lipoma, dermoid cyst, etc).
- **Pulsation**—the swellings arising from the arteries are pulsatile like aneurysms and vascular growths such as carotid body tumor. The swellings which lie just superficial to the artery in close relation with it will pulsate. It is called as '*transmitted pulsation*'. The pulsations which originate in the arterial wall will give rise to '*expansible pulsation*'.
- **Movement with respiration**—this is observed if you are examining the swelling in neck and abdominal area. Swellings arising from the upper abdominal viscera move with respiration.

- *Impulse on coughing*—the swellings which are in continuity with abdominal cavity, pleural cavity, spinal canal or cranial cavity, will give rise to impulse on coughing.
- *Movement on deglutition*—few swellings which are fixed to the larynx or trachea move during deglutition like thyroid swelling, thyroglossal cyst, subhyoid bursitis, pre- or paratracheal lymph node enlargement etc.
- *Movement with protrusion of tongue*—there are some swellings which move with the protrusion of tongue like thyroglossal cyst.
- *Pressure effect*—an axillary swelling with edema of the upper limb means the swelling is probably arising from the lymph nodes. Wasting of distal limb indicates the swelling to be a traumatic one. Sometimes a swelling may be seen in the neck with venous engorgement.

Palpation

- *Temperature*—temperature of the swelling is best felt by the dorsal aspect of the hand. First, note systemic temperature. Place finger of the hand on skin in the area of concern and finger of other hand on skin on contralateral part of body. It is increased in inflammation as there is increased metabolic rate and increased vascularity of area. It is increased in superficial aneurysm, arteriovenous shunt and large recent hematoma.
- *Tenderness*—inflammatory swellings are mostly tender whereas neoplastic swellings are non-tender. When the patient complains of pain due to the pressure exerted by the clinician, the swelling is said to be tender.
- *Size, shape and extent*—deeper dimensions of the swelling remain unknown during inspection. The vertical and horizontal dimensions are better clarified by palpation. Tissue surrounding and underlying bases should be carefully palpated to determine the maximum extension of lesion into the surrounding tissue. Whether the mass is poorly defined or moderately defined or well define should be ascertained (**Fig. 7-51**).
- *Surface*—with the palmar surface of the fingers the clinician should palpate the surface of the swelling. It can be *smooth* (cyst), *lobular with smooth bumps* (lipoma), *nodular* (matted lymph nodes) and *irregular and rough* (carcinoma).
- *Edges and border*—Margins are palpated with the help of tip of the finger. Border of firm process in loose connective tissue is readily determined than soft process in loose connective tissue. If the surrounding normal tissue is of same consistency as the pathological tissue, the border cannot be determined.
 - *Benign swellings*—it has smooth margins whereas malignant growth has irregular margins.

Fig. 7-51: Swelling should be palpated for the consistency, margin and extension of swelling.

- *Acute inflammatory swelling*—acute inflammatory swellings have ill-defined or indistinct margins.
- *Malignancies*—malignancies have ill-defined borders that are extremely difficult to palpate as malignant tumors infiltrate adjacent tissue by extending many processes of the tumor into surrounding tissue.
- *Tumor with extension*—tumor with its extension elicits inflammatory reaction in adjacent tissue which results in sequelae of fibrosis which in turn reveal irregular and diffuse areas that are inflamed and result in more tenacious binding of tumor to the adjacent tissue by an ill-defined border, fibrous attachment whose limit is impossible to perceive by manipulation.
- *Consistency*—the consistency or degree of firmness of the lesion in contrast to that of its surrounding tissue will also affect the ease with which the lesion itself or its border may be identified (**Tables 7.9 and 7.10**). Following terms are used to describe consistency:
 - *Soft*—easily compressible tissue such as lipoma or mucocele and cyst.
 - *Cheesy*—indicates a somewhat finer tissue that has granular sensation but no rebound.
 - *Rubbery*—tissue that is firm but can be compressed slightly and rebound to normal contour as soon as pressure is withdrawn.
 - *Firm*—tissue such as fiber tissue that cannot be readily compressed.
 - *Bony hard*
 - *Modifying factors*
 - Thick layer of overlying tissue especially muscle or fibrous tissue.

Table 7-9: Consistency of normal tissue or organ

Soft	Cheesy
• Adipose tissue	• Brain tissue
• Fascia	Rubbery
• Veins	• Skin
• Loose connective tissue	• Relaxed muscle
• Glandular connective tissue	• Glandular tissue with capsule
• Minor salivary gland	• Arteries and arteriole
• Sublingual salivary gland	• Liver
Firm	Bony hard
• Fibrous tissue	• Bone
• Tensed muscle	• Enamel
• Large muscle	• Dentin
• Cartilage	• Cementum
	• Cartilage

Table 7-10: Consistency of pathological mass

- Soft glandular tissue surrounded by dense connective tissue capsule will be perceived more firm.
- Depth in tissue will alter consistency.
- *Fluctuation*—swelling fluctuates when it contains liquid or gas.

- *Technique*—this test can be carried out by one finger of each hand (**Fig. 7-52**). Sudden pressure is applied on one pole of swelling. This will increase pressure within the cavity of the swelling and will be transmitted equally at right angle to every part of its wall. If another finger is placed on the other side of the swelling the finger will raise passively due to increased pressure within the swelling. This means that swelling is fluctuating. This test is always performed in two planes at right angle to each other. The two fingers should be kept as far as apart as the size of swelling will allow.

Fig. 7-52: Fluctuation test is carried out in patient by using two fingers.

- *Paget's test*—in case of very small swelling which can not accommodate two fingers this test can be performed by simply pressing the swelling at the centre (**Fig. 7-53**). The swelling containing fluid will be softer at the center than its periphery while solid swelling will be firmer at the centre than its periphery. It is called as '*Paget's test*'.
- *Fluid thrill*—in case of swellings containing fluid, a percussion wave is seen to be conducted to its other poles when one pole of it is tapped as done in percussion. In case of big swelling, it can be demonstrated by tapping the swelling on one side with two finger while percussion wave is felt on the other side of the swelling with palmer aspect of the hand (**Fig. 7-54**). In case of small swelling three fingers are placed on the swelling and middle finger is tapped with a finger of the other hand, the percussion wave is felt by other two fingers on each side.

Fig. 7-53: Paget's test is performed in case of small swelling.

Fig. 7-54: Fluid thrill is felt by tapping the swelling.

- *Translucency*—the swelling can transmit light through it. For this it must contain clear fluid like water, serum, lymph or plasma. For this test, darkness is essential. In day time this can be done by using roll of paper which is held on one side of the swelling while a torch light is held on the other side of the swelling. The swelling will transmit the light if it is translucent. The torch light should not be kept on the surface of the swelling, but on one side of the swelling, while roll of paper on the other side so that the whole swelling intervenes between the light and the roll of paper.
- *Impulse on coughing*—on palpation, this test corroborates the finding detected in inspection. The swelling is grasped and the patient is asked to cough. An impulse is felt by the grasping hand. Due to coughing, pressure is increased within the abdominal, pleural, spinal and cranial cavities. This increase in pressure is transmitted to the swelling, where it is felt.
- *Reducibility*—this means that the swelling can be reduced and ultimately disappear as soon as it is pressed upon. This is a feature of hernia, varicocele, meningocele etc.
- *Compressibility*—the swelling can be compressed but would not disappear completely like arterial, capillary or venous hemangioma. The most differentiating features between a compressible swelling and a reducible swelling is that in case of latter the swelling completely disappear as the content are displaced within the said cavities and may not come back until and unless an opposite force such as coughing or gravity is applied, but in the case of the former the content are not actually displaced so the swelling immediately reappears as soon as the pressure is taken off.
- *Pulsatility*—a swelling may be pulsatile if it arises from the wall of an artery or lies close to an artery or if the swelling is a vascular one. Two fingers one from each hand are placed on the swelling as far apart as possible. If the two fingers are raised with each throb of the artery, the swelling is a 'pulsatile' one. When the two fingers are not only raised but also separated with each beat of pulse the pulsation is said to be 'expansile'. When the two fingers are only raised but not separated the pulsation is said to be 'transmitted'.
- *Fixity to the overlying skin*—for this the skin is made to move over the swelling. If it is fixed to the skin, the skin will not move. The skin over the swelling is pinched up in different parts, when the skin is not fixed it can be easily pinched up which may not be possible when the swelling is fixed to the skin. Next attempt is made to move the mass independent of underlying tissue.
 - *Benign lesion*—if it is freely movable then it is benign, possibly encapsulated mass originating in loose subcutaneous tissue or submucosal tissue.
 - *Sebaceous cyst*—sebaceous cyst is freely movable over the underlying tissue but is bound to skin.
 - *Fixed swelling*—swelling may be fixed in fibrosis after previous inflammation episode, infiltrating malignant tumor that originated in skin or mucous membrane and has invaded deep structure, malignancy that originates in deep structure and invade the subcutaneous or submucosal tissue and skin or mucosa and malignancy that originates in loose connective tissue and invade both superficial and deep layer.
 - *Mass in neck*—if fluent mass in neck moves up and down as patient swallows then it must be partly attached to hyoid bone, larynx, trachea, thyroid or parathyroid gland. If it is elevated on protrusive movements of the tongue then it is thyroglossal duct cyst.
- *Relation to the surrounding structures*—The tumor arising from the subcutaneous tissue is free from the overlying

skin and from the underlying contracted muscles. In case of tumor arising from the muscle the swelling can be moved when the muscle is relaxed. Swelling about a bone is absolutely fixed even when the overlying muscle is absolutely relaxed, and cannot be moved apart from the bone.

2 Aspiration

The preoperative aspiration of a fluid-filled mass is worthwhile precautionary procedure, as it should eliminate an unpleasant surprise of opening of an innocuous lesion that may be proved to be a dangerous vascular tumor. Usually it should be carried out before surgery to avoid bacterial infection.

- *Straw colored fluid*—it contains cholesterol crystals in wall that are frequently seen as small shiny particles when syringe is transilluminated. It is seen in some odontogenic and fissural cyst.
- *Thick yellowish white and granular fluid*—it is seen in epidermoid and keratocyst in which lamina is filled with keratin.
- *Yellowish cheesy material*—dermoid cyst contains most of dermal appendage and the aspirate is thickest and fills of yellowish cheesy substance.
- *Sebum*—sebaceous cyst yields sebum which is thick homogenous and yellowish cheesy substance.
- *Amber colored fluid*—dark amber colored fluid of thyroglossal duct cyst.
- *Lymph fluid*—it is colorless with high lipid content, appears cloudy and frothy. It is seen in hygroma and lymphoma.
- *Blue blood*—it is seen in early hematoma, hemangioma and varicosities.
- *Brighter red blood*—aneurysm and arteriovenous fistula.
- *Pus*—aspiration of painful warm fluctuant swelling yields pus.
- *Sulfur granules*—in actinomycosis, it yields pus with few yellow granules in it. These are sulfur granules.
- *Clear viscous fluid*—sticky clear viscous fluid yielded in retention phenomenon.

Other Examination

Other examinations of swelling which are not frequently done in dental office:

- *Percussion*—its role is to find gaseous content within the swelling like resonant note over the hernia or to elicit slight tenderness like Brodie's abscess. Hydatid thrills in case of hydatid cyst.
- *Auscultation*—all pulsatile swellings are auscultated to exclude presence of any bruit or murmur.
- *Measurement*—it is done to find out increase in swelling size at definite intervals but is also to find out if there is any wasting distal to the swelling.

- *Movement of nearby joint*—movement of nearby joint to exclude any impairment.
- *Examination of pressure effect*—nerve may be involved by the pressure of swelling. This will cause wasting, paresis or paralysis of the muscle supplied by the nerve with or without sensory disturbance. The arterial pulse distal to swelling is felt. Sometimes swelling may press on the main artery of the limb and cause weak pulse distally. Swelling may even exert pressure on the adjacent bone by eroding it. It is sometimes seen in aneurysm and dermoid cyst on the skull.

Examination of Ulcer

An ulcer is a break in continuity of the skin and epithelium.

Inspection

- *Size and shape*—the size and shape of the ulcer should be noted. This will yield in diagnosis of the ulcer. The size of an ulcer is important in deciding the time which will be required for healing. A bigger ulcer will definitely take longer time to heal than smaller ulcer. To record exactly the size and shape of an ulcer sterile gauze may be pressed on to the ulcer to get measurement.
 - *Tuberculosis ulcers*—they are generally oval in shape but their coalescence may give an irregular crescentic border.
 - *Syphilitic ulcers*—syphilitic ulcers are similarly circular or semilunar to start with but may unite to form serpiginous ulcer.
 - *Carcinomatous ulcers*—carcinomatous ulcers are irregular in size and shape.
- *Number*—tuberculosis, gummatous, varicose and soft chancre may be more than one in number.
- *Position*—it is very important and often gives clue to the diagnosis. Rodent ulcers are usually confined to the upper part of the face above a line joining the angle of the mouth to the lobule of the ear, occurring frequently near the inner canthus of the eye. Malignant ulcers are more commonly seen on the lips, tongue, breast and penis.
- *Edges*—edges of the ulcer should be properly examined (Fig. 7-55).
 - *Spreading ulcer*—in a spreading ulcer the edges are inflamed and edematous whereas in a healing ulcer the edges, if traced from the red granulation tissue in the center towards periphery, will show blue zone (due to thin growing epithelium) and a white zone (due to fibrosis of the scar).
 - *Undermined edge*—it is mostly seen in tuberculosis. The disease causing the ulcer spreads in and destroys the subcutaneous tissue faster than it destroys the skin. The overhanging skin is thin friable, reddish blue and unhealthy.

Fig. 7-55: Different types of edges of the ulcer—A diagrammatic representation.

- **Punched out edges**—it is mostly seen in a gummatous ulcer or in a deep trophic ulcer. The edges drop down at right angle to the skin surface as if it has been cut out a punch. It is seen in diseases in which activity is limited to the ulcer itself and does not tend to spread to the surrounding tissues.
- **Sloping edge**—it is seen mostly in healing traumatic or venous ulcers. Every healing ulcer has a sloping edge, which is reddish purple in color and consists of new healthy epithelium.
- **Raised and pearly white beaded edge**—it is a feature of rodent ulcer which develops in invasive cellular diseases and becomes necrotic at the center.
- **Rolled (everted) edge**—it is characteristic feature of squamous cell carcinoma or an ulcerated adenocarcinoma. This ulcer is caused by fast growing cellular disease, the growing portion at the edge of the ulcer heaps up and spills over the normal skin to produce an everted edge (Fig. 7-56).
- **Floor**—this is the exposed surface of the ulcer. One must be very careful to note what is there at the floor of an ulcer. When floor is covered with red granulation tissue, the ulcer seems to be healthy and healing. Pale and smooth granulation tissue indicates a healing ulcer. Wash leather slough on the floor of ulcer is pathognomonic of gummatous ulcer. A black mass at the floor suggests malignant melanoma.
- **Discharge**—the character of the discharge should be noted, its amount and smell. A healing ulcer will show scanty serous discharge, but the spreading and inflamed ulcer will show purulent discharge. Serosanguineous discharge is often seen in a tuberculosis ulcer or a malignant ulcer.
- **Surrounding area**—if the surrounding area of an ulcer is glossy, red and edematous, the ulcer is acutely inflamed. Very often the surrounding skin of varicose ulcer is eczematous and pigmented. A scar or wrinkling in the surrounding skin of an ulcer may well indicate an old case of tuberculosis.

Fig. 7-56: Edges, margins and floor of ulcer should be properly examined. In this case, it has got rolled and everted edges of malignancy.

Palpation

- **Tenderness**—an acutely inflamed ulcer is always exquisitely tender. Chronic ulcers are slightly tender. Neoplastic ulcers are never tender.
- **Edges**—in palpation different types of the edge of the ulcer are corroborated with the finding of the inspection. Marked induration of the edge is characteristic feature of a carcinoma.
- **Base**—the student must understand the difference between the floor (exposed surface within the ulcer) and base (on which ulcer rests and it is better felt than seen). If an attempt is made to pick up the ulcer between thumb and the index finger, the base will be felt. Marked induration of the base is an important feature of squamous cell carcinoma and hunterian chancre.
- **Depth**—you should make assessment regarding depth of the ulcer. It can be recorded in the examination sheet in millimeters.
- **Bleeding**—whether the ulcer bleeds on touch should be checked as it is a common feature of malignant ulcer.
- **Relation with deeper structure**—the ulcer is made to move over the deeper structures to know whether it is fixed to any of these structures. A gummatous ulcer over a subcutaneous tissue or bone is often fixed to it. Malignant ulcer will be fixed to the deeper structure by infiltration.

Examination of Sinus or a Fistula

A sinus is a blind track leading from the surface down to the tissue. Fistula is communicating tract between two epithelial surfaces. Both sinus and fistula are lined by granulation tissue which later may become epithelialized.

Inspection

- **Number**—the majority of fistulae which occur in the body are single. Actinomycosis has multiple sinuses and

sometimes ulcerative colitis may produce multiple fistulae.

- **Position**—diagnosis of sinuses and fistulae can be made only by looking at the position of these sinuses and fistulae.
 - **Preauricular sinus** (due to failure of fusion of the ear tubercles) is situated at the roots of the helix or on the tragus of the pinna, direction of the sinus being upwards and backwards.
 - **Branchial fistula** (due to failure of the fusion of second branchial arch with the fifth) brachial arch is almost always situated at the lower third of the neck in front of sternocleidomastoid muscle.
 - **Osteomyelitis**—a single sinus over an irregular lower jaw is mostly due to osteomyelitis.
- **Opening of sinus**—sprouting granulation tissue at the opening of the sinus suggests presence of foreign body at the depth. The opening of tuberculous sinus is often wide and the margins are thin blue and undermined.
- **Discharge**—in osteomyelitis the discharge is often pus while in actinomycosis discharge is of sulfur granules.
- **Surrounding skin**—there may be scar in the surrounding tissue which may indicate chronic osteomyelitis or previously healed tuberculous sinus. There may be surrounding dermatitis and pigmentation, which are characteristic features of Crohn's disease.

Palpation

- **Tenderness**—is the sinus tender? The sinus from inflammatory source will be tender.
- **Wall of sinus**—it is palpated to note any thickening there. Chronic sinus will have thick wall due to presence of fibrosis surrounding the wall of the sinus.

Fig. 7-57: Gutta percha is used to locate the depth of sinus.

- *Mobility*—is the sinus mobile over the deep structure? Sinuses resulting from osteomyelitis are fixed to the bone, which becomes irregular, thickened and tender.
- *Lump*—presence of lump in the neighborhood of a sinus often indicates tuberculosis lymphadenitis.
- *Probe examination*—this will inform the clinician about the direction and the depth of the sinus. It will also detect presence of any foreign body which will be movable at the depth of the wound and whether fistula is communicating with a hollow viscous or not and whether fresh discharge comes out on withdrawal of the probe or not.
- *Depth of sinus*—it is done with the help of radiograph. A gutta percha point is inserted in the sinus and radiograph is taken (Fig. 7-57). As gutta percha points are radiopaque it will locate the exact direction and depth of the sinus.

Examination of Cranial Nerves

In evaluating patients with oral sensory or motor complaint, it is important to know whether there is any objective evidence of abnormality of cranial nerve function that might relate to the patients oral symptoms. The routine cranial nerve evaluation is systematically carried out according to the sequence of cranial nerve from I to XII.

Olfactory Nerve

- *Procedure*—it is traditionally tested by closing one of the patient nostrils with a finger and asking him if he can smell a strongly scented volatile substance such as coffee or lemon extract. The test is then repeated with other nostril. The patient should sniff strongly to draw the volatile molecules well into the nose (Fig. 7-58).

Fig. 7-58: Smelling of volatile substance from nostril will test for olfactory nerve.

- *Precaution*—such a procedure tests for olfactory nerve function only when the nasal airway is patent to the olfactory receptors and when the substance being tested does not produce a response from the patient solely on the basis of chemical irritation of non-specific somatic sensory receptors in the nasal mucosa.

Optic Nerve

- *Ophthalmoscope*—it is tested by investigation of visual acuity and the visual fields and those trained in the use of the ophthalmoscope can use this instrument to examine the ocular fundus directly for lesions.
- *Wall chart*—visual activity can be tested with the familiar wall chart but can also be evaluated by asking the patient to read print of various sizes in a book or newspaper held at various distance from the patient eye.

Trigeminal Nerve

- *Significance*—it is tested for both motor and sensory functions. A small motor branch of this nerve supplies the muscle of mastication, and strength of these muscles is used as measure of the intactness of their motor supply.
- *Palpation while patient clenches*—the force of contraction and muscle bulk of the masseter and temporal muscles are noted by external palpation of these muscles bilaterally while the patient clenches (Fig. 7-59). Lateral movement of the jaw against the examiner's finger is one test of pterygoid functions.
- *Displacement against resistance*—another useful test of motor power of the masticator muscles is to check their ability to carry out voluntary displacement of the jaw against the imposed resistance of the examiner's hand. Place your thumb on molar table with fingers externally about the body and ramus of mandible. The patient

Fig. 7-59: Test for motor function of trigeminal nerve, patient clenches and doctor palpate masticator muscle.

moves the jaw forward, sideways and upward his head steadied by your other hand.

- *Percussion hammer test*—abnormalities of the jaw jerk may indicate muscular weakness or an abnormality of the proprioceptive reflex arc controlling jaw movement. Press your index finger downward and posteriorly above the mental eminence and lightly strike the finger with a percussion hammer or with one or two finger of the other hand.
- *Graded von Frey hairs*—for testing of trigeminal sensory function ‘graded von Frey hairs’, a series of fine hairs or nylon fibers calibrated according to the force required to bend the filament when it is placed against skin, mucosa or tooth, esthesiometers often designed with a pistol grip to facilitate placement of the points of the instrument on the oral mucosa and calibrated thermal device for application of hot and cold can be used.

Facial Nerve

- *Significance*—the facial nerve is tested for abnormalities of motor function involving the ‘mimetic’ muscle of facial expression and also gustatory disorders. A gustosalivary reflex involves facial nerve gustatory stimuli and increase salivary function.
- *Lemon juice application*—Affected chorda tympani may be associated with failure of salivary flow to increase following application of lemon juice or citric acid to the affected side of the mouth.
- *Motor function test*—motor function of facial nerve is tested by observing facial muscle function in response to request to wrinkle (**Fig. 7-60**) the forehead, frown, close the eyelid tightly, open the mouth, retract the mouth, blow out the cheek, pucker the lips, screw up the nose, whistle and speak.

Glossopharyngeal Nerve

It provides taste fibers to the posterior aspect of the tongue, somatic sensory fibers to the same area of the tongue as well as pharynx and soft palate and motor fibers to the stylopharyngeal muscle that plays only minor role in palatal function, preventing any accurate testing of 9th cranial nerve functions.

Vagus Nerve

- *Significance*—the vagus nerve is the chief motor nerve of the pharynx and larynx and also provides sensory fibers to the pharyngeal and faucial mucous membrane
- *Pharyngeal movement observation*—routine testing is carried out by observation of pharyngeal movements’ i.e. symmetrical elevation of the soft palate and shortening of the uvula when the patient says ‘ah’ and

Fig. 7-60: Patient is asked to wrinkle his forehead for motor function test of facial nerve.

pharyngeal and gag reflex, i.e. contraction of the palate and faucial muscles in response to touching the mucous membrane of the posterior pharynx.

Hypoglossal Nerve

It provides motor supply to the tongue; hypoglossal paralysis causes deviation of the tongue when patient extrudes it. Atrophy of tongue musculature may be noted on oral examination and its muscular tonus by the force with which the patient can push the tongue against either cheek or by evaluation of the tongue jerk.

Establishing the Diagnosis

Provisional Diagnosis

All the records and clinical findings clubbed together, clinician should be able to frame a provisional diagnosis. Clinician should keep in mind the differential diagnosis of the lesion. In provisional diagnosis you should list all those items that either indicate an abnormality or suggest the possibility of significant health problems requiring further evaluation.

Investigations

Laboratory investigations help to come to the final diagnosis, e.g. in case of caries (proximal) the provisional diagnosis will be mesial or distal caries. Radiograph will confirm the diagnosis and help us to differentiate it into incipient, moderate, advanced and severe. To confirm the

Table 7-11: Case history format

Personal information	• Clubbing • Cyanosis	Cheek

		• Planned treatment

diagnosis, one should proceed with available methods of investigation.

The common methods are radiological, hematological investigations, urine analysis, biochemical investigations, histopathological investigations, microbiological investigations and special investigations like sialography, MRI etc.

Final Diagnosis

The final diagnosis can usually be reached following chronologic organization and critical evaluation of the information obtained from the patient history, physical examination and the result of radiological and laboratory examination.

The final diagnosis usually identifies the diagnosis for the patient's primary complaint first, with subsidiary diagnosis of concurrent problems. Previously diagnosed conditions that remain as actual or potential problems are also included, with comment by 'history' 'previously diagnosed'.

In case of no definite diagnosis is made diagnosis should be written as idiopathic, unexplained, functional and symptomatic.

The patient should be informed of the diagnosis, results of tests and examination.

Making a Treatment Plan and Medical Risk Assessment

The formulation of an appropriate treatment plan will depend on both knowledgeable, experienced, competent clinician and nature and extent of treatment facilities available. Details of medical or surgical treatment, which the patient has received, should be known. Evaluation of any special risks posed by the patient's compromised medical status in the circumstance of the planned anesthetic diagnostic or surgical procedure.

Medical risk assessment is also needed to identify the need of medical consultation and to recognize significant deviation from normal health status that may affect dental management.

American Society of Anesthesiologists Physical Status Classification

- P1—a normal healthy patient
- P2—a patient with mild disease
- P3—a patient with severe systemic disease that limits activity but no incapacitating
- P4—a patient with an incapacitating systemic disease that is a constant threat to life
- P5—a Mir bund patient who is not expected to survive without operation
- P6—a declared brain dead patient whose organs are being removed for donor purpose

Adapted from American Society of Anesthesiologists

Table 7-12: Medical questionnaire to be asked to the patient in medical examination

System	Question to be asked
General	• Are you now or recently been under a physicians care? if so, what is the condition being treated? • Have you been hospitalized during past 2 years? • Do you take prescription or non-prescription medicines on a permanent or non-permanent basis? • Do you have any allergies, if so to what? • Aspirin • Sulphur containing drugs • Penicillin or any other antibiotics • Codeine or any narcotic • Dental anesthetic or • Any specific drug • Does dental treatment make you nervous?
Cardiovascular system	• Chest discomfort on exertion, when eating or at rest • Tightness of the chest • Palpitation • Fainting • Ankle edema • Shortness of breath • High or low blood pressure • Heart murmur.
Respiratory system	• Dyspnea on exertion • Wheezing, coughing, excessive sputum production • Coughing up blood.
Blood disorders	• Prolonged bleeding during cut, tooth extraction or other injury • Do you bruise easily • Required a blood transfusion • Have frequent infections • Have ever been told that you were anemic.
Nervous system	• Head-injury or concussion • Seizures/black-outs/fits • Frequent headaches • Experienced any pain, numbness, or tingling in your face , arms or legs • Had any paralysis.
Metabolic-endocrine system	• Any recent loss or gain of weight • Hyperthyroidism or hypothyroidism • Do your hands sweat excessively • Are you easily fatigued?
Gastrointestinal, hepatic, biliary tracts	• Difficulty in swallowing • Heart-burn or belching • Episodes of nausea and vomiting • Vomited blood • Frequent stomach or abdominal pain • Recently had a change in bowel habits • Frequent episodes of diarrhea • Ever noticed bright-red, or black colored stools.
Genitourinary system	• Urinate frequently • Difficulty or pain during urination • Ever passed brown or red urine • (for females) had abnormal or irregular menstrual period

- Drugs given to the patient, dose and duration of treatment—the drug can be prescribed in following formats.
 - *OD—Omni Die*
 - *B.I.D.—Bis in Die*
 - *B.D.S.—Bis in die sumendus*
 - *T.I.D.—Ter in Die*
 - *T.D.S.—Ter die sumendum*
 - *Q.I.D.—Quater in die*
 - *Q.D.S.—Quater die sumendum*
 - *S.O.S—*as and when required (si. opus sit)
 - *H.S—*Hora somni
 - *Rx—*Take though
- *Prescription writing*
 - *Superscription*—general background information regarding the dentist (name, address and telephone number), the patient (name, address, age) and the date the prescription is written.

- *Inscription*—specific information regarding the drug (generic or proprietary name or both) and the dosage.
- *Subscription*—direction to the pharmacist for filling the inscription (number of capsules or tablets to be dispensed or the volume of liquid), the number of refills allowed and time constraints, directions to be listed on the container label.
- *Transcription*—instruction to the patient, to be listed on the container label.
- *Signature and educational degree of prescribing doctor*—a signature is required by law only for certain controlled substance (schedule II drug).
- *Guidelines for prescription writing*
 - Obtain an accurate and complete patient history, including whether the patient is taking any drugs prescribed by other doctors or any over the counter drugs; both can affect the dosage or effects of the drug being prescribed.
 - Use separate prescription blank for each drug ordered. Avoid using prescription blank with trade names printed on them.
 - Never presign prescription blank and always store blank prescription pads in a secure place.
 - Write out number than using digits so that prescription cannot be altered.
 - Prescribe sufficient drug and at adequate dosing intervals to maintain therapeutic blood level.
 - Keep the record of all drugs prescribed for each patient.
 - Instruction listed on the drug container for the patient must be specific. Full disclosure is verbally given regarding the prescription before the patient leave

the office. Stress the need to consume all of the prescribed medication, as in taking the antibiotics even if the patient is feeling better before the prescribed amount is taken.

- Instruction regarding anticipated side effect as well as the use of alcohol with taking the prescribed drugs should be explained to the patient verbally. Advise the patient to call the office when side effects develop.
- Cost factor should be considered when prescribing medication.
- *In surgical treatment*
 - Types of anesthesia; local or general anesthesia
 - Anesthetics used
 - Name of the anesthetist
 - Name of the surgeon
 - Closure
 - Drainage given or not
- *Follow up*—these resume when the patient is discharged from the hospital and extends till he starts his normal active life.

Investigation in Dentistry

Introduction

There are various important investigations which are required for the diagnosis and treatment plan of various disorders related to the oral cavity. Laboratory studies are an extension of physical examination in which tissue, blood, urine or other specimens are obtained from patients and subjected to histological, bio-examination, microbiological or immunological examination. Information obtained from these investigations help in identifying the nature of the disease.

Diagnostic Test for Cancer Detection

The earliest is the diagnosis of the oral cancer, best is the prognosis of the cancer. In cancer, cellular and tissue alteration occurs. This fact is kept in mind for the entire diagnostics test for cancer detection.

Classification

- *Clinical method*
 - Vital staining—toluidine blue method and Lugol's iodine method
 - Vizilite
 - Acridine binding method
- *Photodiagnosis*
 - 5-Aminolevulinic acid mediated fluorescence endoscopic imaging
 - 5-Aminolevulinic acid mediated digitized fluorescence endoscopic imaging
 - Autofluorescence spectroscopy
 - Fluorescence photography
- *Histopathological methods*
 - Biopsy
 - Exfoliative cytology
 - Oral CDx system
- *Molecular methods*
 - Quantification of nuclear DNA content
 - Tumors markers
 - Microsatellite markers.

Clinical Method

Toluidine Blue Staining

The use of Toluidine blue (tolonium chloride) dye as a mouthwash or topical application is currently receiving much attention as an aid to the diagnosis of oral cancer and potentially malignant lesions. The method has good sensitivity with a very low false negative rate. The dorsum of the tongue always stains positively, due to the retention of dye in crevice between the papillae. It is effective in demonstrating dysplasia and early malignant lesion which is not clinically recognizable.

Mechanism

- *Binding with DNA*—it is an acidophilic, metachromatic nuclear dye of thiazine group that selectively stains acidic tissue components particularly nucleic acid such as DNA and RNA. Dysplastic and anaplastic areas which contains more DNA than normal cells.
- *Intracellular canal*—malignant epithelium contains intracellular canals that are wider than normal epithelium, which also facilitates the penetration of dye.
- *Effect on normal epithelium*—most of the epithelial surfaces stain blue after the application of 1% toluidine blue solution but the stain is lost after application of 1% acetic acid solution to normal epithelial surface or benign erythematous lesions on oral mucosa.
- *Effect on benign ulceration*—benign ulceration has well defined uptake of dye at the margins whereas, diffuse marginal pattern is characteristic of dysplasia or malignancy.

Availability

It is readily available to use kit as 3 component system. First contain 1% toluidine blue 10 ml solution. Second and third kit contains 1% acetic acid as pre- and post-rinse solution.

Contents

- Toluidine blue—1 gm
- Acetic acid—10 cc
- Absolute alcohol—4.19 cc
- Distilled water—86 cc
- pH adjusted to 4.5

Technique

- *Rinsing*—initially you ask the patient to rinse the mouth twice with water (20 seconds each). After rinsing with water, ask patient to rinse with 1% acetic acid (20 seconds).
- *Drying of area*—you should gently dry suspicious mucosal areas with gauze. You have to take care not to abrade the tissue while drying.
- *Application of toluidine blue solution*—apply 1% toluidine blue solution to the lesion with a cotton swab.
- *Rinsing*—ask patient to rinse again with acetic acid (approximately 150 ml for one minute). After rinsing with acetic acid, then ask patient to rinse with water.
- *Positive staining*—if the mucosa is stained positive (**Fig. 8-1**), you have to repeat the procedure in one to two weeks. Biopsy of all sites is advised, which stain positive on two successive visits.

Fig. 8-1: Positive toluidine blue staining showing uptake toluidine blue by dysplastic mucosa (Courtesy Zila Pharmaceutical).

Lugol's Iodine Test

It is retained in normal squamous epithelial cells but not in dysplastic or malignant cells of the squamous epithelium. The use of Toluidine blue application in combination with Lugol's iodine solution may offer potential advantage. The Toluidine blue will stain the abnormal (reactive and dysplastic) epithelium whereas, Lugol's iodine solution will bind to glycogen present in normal epithelium.

In the oral tissues, Lugol's iodine has less sensitivity in identifying oral premalignant and dysplastic diseases. But, is of greater specificity.

Contents

- Iodine—2 gm
- Potassium iodide—4 gm
- Distilled water—100 cc

Mechanisms

- *Reaction with glycogen*—Lugol's iodine solution produces a brown black stain by reaction of iodine with glycogen. Iodine is removed by fixation in alcohol and formaldehyde.
- *Effect on proliferating epithelium*—glycogen content is inversely related to the degree of keratosis, suggesting a role of glycogen in keratinization. So when proliferating epithelium is present it is usually poorly stained or unstained.
- *Effect on inflammatory tissue*—there is relationship between the degree of inflammation and glycogen content. So in this case, tissue will stain dark brown.

Vizilite

Vizilite is non-toxic chemiluminescent light that is shined in the mouth. Tissue which are not normal, they glow differently, as compared to normal tissue. This will make them more visible. Vizilite will be more useful for the detection of biopsy proven squamous cell dysplasia which is not seen with naked eye.

Contents

- Vizilite rinse—1% acetic acid solution
- Vizilite capsule—chemiluminescent light stick
- Vizilite retractor—sheath and handle

Mechanism

- *Physics*—normal tissue absorb Vizilite and as a reason they appear dark. This is not the case with dysplastic cells. In case of dysplastic cells nucleus become larger, resulting in reflection of light and gives white appearance.

Technique

- *Application of Vizilite rinse*—acetic acid solution should be applied first. This will result in change in refractile properties of lesion like leukoplakia. The change will occur in the cells as acetic acid is cytoplasmic dehydration agent and there is increased nuclear-cytoplasmic ratio in atypical keratinized mucosa.
- *Visualizing the mucosa with Vizilite*—then chemiluminescent capsule is projected on the mucosa. The abnormal mucosa like dysplastic mucosa will show more reflection of light and will appear whiter as compared to normal mucosa (Fig. 8-2).

Fig. 8-2: In Vizilite testing, dysplastic mucosa will show appearing whiter as compared to adjacent mucosa (Courtesy Zila pharmaceutical).

Acridine Binding Method

In this method, the uptake of acriflavine by desquamated buccal cells is measured. Since the DNA content of the dysplastic cells are more, they will stain more intensely than normal cells.

Photodiagnosis

This optic method is used for the early diagnosis. It is based on fluorescence measurement. Light induced fluorescence (LIF) spectroscopy is useful for the early cancer detection in oral cavity. The principle is that there is endogenous tissue fluorescence of photosensitizer which is accumulated in tumor tissue. Photosensitizer which can be used are m-THPC and delta aminolevulinic acid.

5-aminolevulinic Acid (ALA) Mediated Fluorescence Endoscopic Imaging

- *Source*—aminolevulinic acid is precursor in biosynthesis of heme and it induces the production of endogenous photosensitizer protoporphyrin.
- *Mechanism*—after oral administration of ALA, synthesis of protoporphyrin occurs in dysplastic cells. This will result in fluorescence and can be easily detected.

5-aminolevulinic Acid Mediated Digitized Fluorescence Endoscopic Imaging

It is same method as above with digitalization facility. It has capability of high quality images and it can measure the fluorescence effect of diseased oral tissue.

Autofluorescence Spectroscopy

- *Use*—autofluorescence spectroscopy is non-invasive method. It is used for detection for alteration in the structural and chemical composition of cells. It is also useful for optimal location of biopsy.
- *Mechanism*—autofluorescence occurs due to endogenous fluorophores. It consists of fluorophores from tissue matrix molecule, intercellular molecules like collagen, elastin and nicotinamide adenine dinucleotide phosphate.

Fluorescence Photography

The basic principle behind this is that, by repeated fluorescence photography, it will show reduction and diminution of positive fluorescence associated with cancer regression and vice versa. This is useful as an adjunct aid in the diagnosis of squamous cell carcinoma.

Histopathological Examination

Biopsy

It is a process of surgically removing tissue from a patient for histopathological examination. It is the removal of sample tissue from living individuals. It provides valuable information in determining the prognosis and type of treatment required.

Indications

- *Undiagnosed clinical condition*—after careful clinical examination, if any alteration from normal is seen and it is not possible to identify the condition clinically, a histopathological investigation is necessary.

- *Nature of lesion*—to evaluate the exact histological nature of any soft tissue or intra-osseous lesion.
- *Screening test*—to screen abnormal tissues removed from oral cavity including granuloma and cyst.
- *Detection of malignancy*—to confirm the existence and nature of directly apparent malignancy so that the treatment can be undertaken immediately.
- *Diagnostic test*—diagnostic tests for evaluation of non-neoplastic lesions such as mucosal nodules, papilloma, erosive lichen planus, erythema multiforme, lupus erythematosus, pemphigus, pemphigoid and desquamative gingivitis.

Avoidance of Delay for Biopsy

Biopsy should not be delayed when following feature are present.

- *Rapid growth*—rapid increase in size of the lesion that cannot be explained by inflammation, edema and opening of new vascular channels.
- *Absent local factors*—absence of any recognized irritant, particularly when the lesion is chronically ulcerated or bleeds spontaneously.
- *Fixed lymph node enlargement*—presence of firm regional lymph nodes, especially when they are seen to be fixed to surrounding tissues.
- *Root resorption with loosening*—destruction of tooth roots and loosening of teeth with evidence of rapid expansion of the jaw.
- *History of malignancy*—history of cancer elsewhere in the body, previous history of oral cancer and radiation therapy.

Uses

- *Diagnosis*—biopsy is useful for the diagnosis of pathologic lesions. It also helps in determining neoplastic and non-neoplastic lesions of oral cavity.
- *Grading of tumors*—it aid in determining the grading of tumor.
- *Metastatic lesion*—it is also useful for the diagnosis of metastatic lesions.
- *Recurrence*—for the evaluation of recurrence.
- *Management assessment*—it is useful for the therapeutic assessment of the lesion by differentiating between benign and malignant lesion.

Types of Biopsy

More commonly used biopsies are excisional, incisional, fine needle, punch, scrape and trephine. Some biopsy like bite, cone, core, endoscopic, irrigation, pressure, shave and sponge are less commonly used.

How to Submit Biopsy Specimen

- *Information written on specimen*—the submission of specimen should be accompanied by the date of biopsy, name, age and sex of the patient, the area from where biopsy specimen is taken and brief description of clinical appearance of lesion and associated symptoms, along with tentative clinical diagnosis. The biopsy specimen should not only include the lesion but also the adjacent clinically normal tissue.
- *Sectioning of biopsy specimen*—as soon as possible after the surgical procedure, carefully section the biopsy specimen with a fresh scalpel or razor blades into pieces. Pieces should not be larger than 0.5 cm in diameter, identifying each fragment in relation to the overall specimen and lesion.
- *Avoid surface with iodine*—iodine containing antiseptics should be avoided with surface since they have a tendency to stain certain tissue cells permanently.
- *Fixing solution*—the portion of the biopsy specimen to be used for routine histological study should be placed at once in a suitable fixing solution. Fixative which is used is Karnovsky's fixative (4% paraformaldehyde) and 5% glutaraldehyde in 0.1 M solution for 2 to 4 hours and delivers promptly to the laboratory.
- *Stains*—many different types of stains are used in diagnostic pathology (Fig. 8-3).

Fig. 8-3: Different types of stains used in diagnostic pathology.

- *Submission of teeth*—for the histologic examination of teeth, the apex of tooth should be clipped with a pair of pliers or a small hole should be drilled into the radicular pulp with dental burr to allow penetration of the fixative.
- *Preservation*—the excellent preservation of cellular detail required is obtained by following methods.
- Cutting the specimen into tiny blocks before fixation.
- Use of special fixatives that preserve cellular detail with minimum disruption from rapid dehydration or osmotic shock.

- Post-fixation and processing of tissues in the laboratory after the initial period of pre-fixation (**Fig. 8-4**).

Fig. 8-4: Biopsy slide is prepared and stored properly.

Instrument and Materials

- *Excisional and incisional*—Local anesthesia with vasoconstrictor, scalpel holder and blade. Pointed surgical scissors, tissue forceps and surgical hemostat. Sterile sponge, curved needles and suture, needle holder. Wide mouthed bottle containing 10% formalin.
- *Intraosseous biopsy*—periosteal elevator, bone bur, curette.
- *Aspiration biopsy*—large syringe (10–20 cc) with a large needle.

Excisional Biopsy

Total excision of a small lesion for microscopic examination is called as '*excisional biopsy*'. It is a therapeutic as well as a diagnostic procedure. Normal tissue on the margins of the lesion should be included.

Indications

- *Small lesion*—it is the preferred treatment if, the size of lesion is such that it may be removed along with the margins of normal tissue and wound can be closed primarily. It is usually done in case of lesion smaller than 1 cm.
- *Sessile lesion*—when the lesion is sessile or pedunculated, excisional biopsy can be done.
- *Movable tissue*—tissues which are freely movable and located above the mucosa or just beneath the surface.

Procedure

- *Local anesthesia*—anesthetize the lesion with 2% local anesthetic containing vasoconstrictor. Care is taken not to inject directly into the lesion that is to be removed.
- *Elliptical incision*—with the scalpel, make an elliptical incision on either side of the base of the lesion so that incision line intersected. The blade should be at an angle of 45° towards the center of the lesion.
- *Pulling of tissue*—outward tension is placed on the lesion by means of suture or with the help of tissue forceps

attached at the edge of specimen. Care must be taken not to crush the specimen.

- *Dissection of tissue*—the specimen is now gently dissected out with either a scalpel or a pair of surgical scissors.
- *Keeping in formalin solution*—the tissue must be immediately submerged in 10% formalin solution.
- *Suturing*—surgical site is closed with either silk or absorbable sutures placed approximately 5 mm apart.

Incisional Biopsy

Incisional biopsy can be performed by removing a wedge shaped specimen of the pathological tissue along with surrounding normal zone.

Indications

- *Large lesion*—if the lesion is large and diffuse and extends deeply into the surrounding tissue so that total removal cannot be obtained easily with local anesthesia, an incisional biopsy is indicated.
- *To determine nature of treatment*—lesions in which diagnosis will determine whether the treatment should be conservative or radical.

Procedure

- *Selection of site*—the selection of site is important. It is best to select the site away from an obvious ulceration or area of necrosis, as these are areas of intense inflammation which make interpretation difficult.
- *Local anesthesia*—the tissue around the specimen is infiltrate with 2% local anesthetic.
- *Elliptical incision*—with a scalpel, make an elliptical incision encompassing the selected area of the lesion. The incisional lines must be deep enough to include underlying connective tissue to the level of muscle or bone.
- *Suturing*—suture is inserted through the end; upward tension is applied while tissue sample is dissected out.

Intraosseous Biopsy

It is less frequently performed. It may be in the form of exploratory curettage in which the representative tissue is obtained to determine the nature of large radiological alterations.

Procedure

- *Selection of site*—after correlating the radiographs with overlying anatomical structures, the site of which the mucoperiosteal flap is to be raised is selected.
- *Local anesthesia*—anesthesia to the area is accomplished by block injection to the area and with local infiltration

with a 2% solution of local anesthetic along with vasoconstrictor.

- *Incision lines*—with a scalpel, press firmly against the cortical bone, outline the flap using the periosteal elevator and strip the tissue from the bone.
- *Drilling by bur*—using a small bone bur in low speed drill, make a small square window through cortical plate; using a water spray as a coolant.
- *Removal of cortical plate*—remove the cortical plate of bone and with curette, obtain deep sample of the underlying lesion and place the sample in 10% formalin.
- *Closing of flap*—the surgical site is closed by replacing the flap.

Punch Biopsy

It is rarely necessary in the oral cavity as most of the oral lesions are easily accessible. With this technique the surgical defect that is produced is small and does not require suturing.

In this technique, a sharpened hollow tube (Fig. 8-5); several millimeters in diameter is rotated until underlying bone or muscle is reached. The tissue is then removed in the same manner as in incisional or excisional biopsy.

Fig. 8-5: Different types of punch of different diameter are used in punch biopsy.

Frozen Section Biopsy

It is performed in order to get an immediate histological report of a lesion. It is done to determine whether a lesion is malignant or not. It is also used to evaluate the margins of an excised cancer, to ascertain that the entire lesion is removed at the time of surgery.

The tissue is obtained from lesion and it is kept in deep freeze and then frozen tissue is sectioned and stained to get a prompt diagnosis. In this type of biopsy, the slides cannot be preserved for future reference.

Exfoliative Cytology

In this, the surface of the lesion is either wiped with some sponge material or scraped to make a smear. It is the

microscopic examination of the cells shed from an epithelium. The appreciation of the fact that some cancer cells are so typical that they can be recognized individually has allowed the development of this diagnostic technique, which is developed by Dr. George Papanicolaou Who is also known as the 'father of cytology' and the technique is called as *Pap smear* (Fig. 8-6).

Fig. 8-6: Pap smear (Courtesy Dr Akshay Dhoble).

Principle of Pap Smear

- *Normal cells*—individual cells can often be diagnosed as such microscopically by their large size, their pleomorphism, increased nucleocytoplasmic ratio, hyperchromatism and prominence of nuclei and their abnormal mitosis.
- *Dysplastic cells*—cancer cells exfoliate more easily than normal cells most likely due to their lowered cohesiveness as a result of either decrease in number of tight junctions or lower calcium content.

Advantages

- *Time saving*—cytology is quick procedure so it saves lot of time. It is simple procedure.
- *Painless*—as it is painless, it causes minimum discomfort to the patient.
- *Low cost*—cost of performing cytology is less as compared to cost of biopsy.
- *No anesthesia*—it does not require anesthesia.
- *False negative biopsy*—it helps to check against false negative biopsy.
- *Follow up*—it is especially helpful in a follow up detection of recurrent carcinoma.
- *Screening test*—it is valuable for screening lesions whose gross appearance is such that biopsy is not warranted.
- *Safety*—it is a safe procedure as complications are rare.
- *Rapid diagnosis*—it enables a rapid diagnosis.

- *Bloodless procedure*—as it is bloodless procedure there is less risk of delayed wound healing and infection.
- *Accuracy*—there are report of 100% accuracy in lymph node aspiration from metastatic carcinoma, melanoma, Hodgkin's and Non-Hodgkin's lymphoma.

Disadvantages

- *Firm tumors*—firm tumors may prevent a proper cytodiagnosis due to paucity of cells in the aspirate.
- *False negative results*—oral cytology can give false –ve findings due to inadequate sampling. Another reason for this is many lesion have a thick keratinized surface layer and contain subtle change of dysplasia.
- *Non-assessment*—some specimens cannot be assessed due to poor cellularity.

Indications

- *Patient preference*—as a compromise, when the patient refuses for biopsy.
- *Follow-up*—as a means of follow-up for recurrence in patients who had radiation therapy for the lesion that was superficial or adjacent to bone, periodic recall of high risk patient.
- *Debilitated patients*—in place of biopsy, when dealing with extremely debilitated patients possessing problems to determine a suitable biopsy site.
- *Adjunct test*—as an aid to the diagnosis of some dermatological diseases such as Pemphigus, White sponge nevus, oral malignant and pre-malignant lesions.
- *Periodic review*—periodic review of oral lesion like leukoplakia, lichen planus should be carried out by this method.
- *Rapid evaluation*—for rapid evaluation of an oral lesion that on clinical grounds, is thought to be malignant or pre-malignant and for which, the dentist is unable to obtain permission for a biopsy.
- *Sequential laboratory evaluation*—for sequential laboratory evaluation of an area of the mucosa that has previously been treated by radiation or by excisional biopsies to remove malignancy.
- *Vesicular lesion*—for evaluation of vesicular lesions where facilities for rapid evaluation of Tzanck smears are not available.
- *Population screening*—when population screening is done for the detection of oral cancer exfoliative cytology is the recommended method.

Instruments Used

Instrument which are used in exfoliative cytology are glass microscopic slide, lead pencil, cement spatula or wax carver, wooden tongue depressor, toothpick, canister of cytospray and 95% isopropyl alcohol or ethyl alcohol.

Procedure

- *Information to written on slide*—use of two slides for each site to be sampled. With lead pencil print the patient's name, date when the slide is prepared and the site of the lesion on frosted end of glass microscopic slide.
- *Instrument*—the instrument selected to remove the superficial cell must have a square edge with a contour sufficient to scrape off the superficial layer of cells. When the lesion is very small, the edge of toothpick is effective.
- *Clearing of surface*—clear the surface of oral lesions with debris and mucus.
- *Scraping the tissue*—while the tissue is stretched, the squared edge of the collection instrument is positioned at the back of the lesion and is firmly held and brought forward and pressure applied until visible material is collected. Vigorous scraping of the entire surface of the lesion several times is done with a metal cement spatula or a moistened tongue blade.
- *Spreading of material on microscopic slide*—collected material is then quickly spread evenly over the microscopic slide.
- *Fixing of tissue*—fix it in commercial preparation such as spraycyte, 95% alcohol or equal part of alcohol and ether, immediately before it dries. Then allow it to stand for thirty minutes so that it air dried.
- *Repeat*—repeat the procedure and prepare a second smear.

Interpretation

It is reported by a cytologist as follows into one of the following five classes:

- *Class I (normal)*—it indicates that only normal cells are observed.
- *Class II (atypical)*—presence of minor atypia but no evidence of malignant changes.
- *Class III (indeterminate)*—this is a stage in between that of class II and IV and separates non-cancer cells from cancer cells displaying wider atypia that may be suggestive of cancer but they are not clear-cut and may represent pre-cancerous lesion or carcinoma *in situ* and a biopsy is recommended in such cases.
- *Class IV (suggestive of cancer)*—few cells with malignant characteristic or many cells with borderline features. Biopsy is mandatory in such cases.
- *Class V (positive of cancer)*—cells that are obviously malignant. Biopsy is mandatory in such cases.

Fine-Needle Aspiration Cytology

It is the microscopic examination of an aspirate obtained by inserting a fine needle into the lesion. It is a painless

and a safe procedure for rapid diagnosis. First discovered by Kun in 1847 and reintroduced in 1930 by Martin and Ellis.

Indications

- *Salivary gland pathology*—FNAC of salivary glands is a useful procedure for evaluation of salivary gland tumors.
- *As replacement for extensive biopsy*—it is indicated in lesions in which open biopsy require extensive procedures.
- *Suspicious lymph nodes*—for examination of enlarged clinically suspicious lymph nodes.
- *Recurrence*—to check against recurrence or local extension.
- *Metastatic lesion*—detection of metastatic sq. cell carcinoma within cervical nodes.

Procedure

- *Needle positioning*—first you have to position the needle within the target tissue.
- *Application of negative pressure*—plunger is pulled to apply negative pressure. Needle is moved back and forth within the target tissue to obtain a greater field.
- *Releasing of negative pressure*—negative pressure is then released while the needle remains within the target tissue.
- *Withdrawing the needle*—needle is withdrawn and then the defumed air drawn in the syringe and the aspirate is blown onto the slide.
- *Fixing*—fixing is done in 95% alcohol for 1 hour for Pap stain and a little prolonged for HE stain.

ORALCDX Test

It is highly specialized computer assists analysis of an oral brush biopsy performed on oral tissue. It is the most recent development in oral biopsy technique. This technique is ideal for determining the need for scalpel biopsy in benign-appearing oral mucosal leukoplakia.

Procedure

- *Collection of sample cells*—this technique utilizes a disposable brush to collect a transepithelial sampling of cells (**Fig. 8-7**).
- *Computer screening*—the sample is screened by computer which is programmed to detect cytologic changes associated with premalignancy and squamous cell carcinoma. The computer consists of neural network based image processing system specially designed to detect oral epithelial precancerous and cancerous cells.

- *Image processor*—this is specially designed to detect as few as two abnormal epithelial cells scattered among more than thousand cells on each biopsy specimen.

Interpretation

The specimen is reviewed by a pathologist for final diagnosis.

- *Negative results*—it indicated no epithelial abnormality.
- *Positive results*—it indicated definitive cellular evidence of epithelial dysplasia. Patient should be referred to scalpel biopsy.
- *Atypical results*—it indicates abnormal epithelial changes. This should be referred to scalpel biopsy.

Fig. 8-7: Use of disposable brush to collect sampling of cells in oral brush biopsy.

Molecular Methods

Quantification of Nuclear DNA Content

Principle

The DNA content of nucleus is dependent upon the number of chromosomes. In case of epithelial dysplasia and malignancy there can be polyploidy (more number of chromosomes) or aneuploidy (abnormal number of chromosome). So quantitative analysis of DNA content reflects the total chromosomal content.

Procedure

It is done by flow cytometer analysis. Flow cytometer is automated, precise, reproducible, reliable and objective measuring device of cellular DNA content. Limitation of flow cytometer analysis is that it scans only severe dysplasia of detectable oral premalignancy.

Tumors Markers

Tumor markers are defined as biochemical substances synthesized and released by cancer cells. Tumor markers may be produced by host in response to cancerous substances. Tumors markers can be seen in blood circulation, body cavity fluids, cell membrane and cell cytoplasm.

In oral cavity no markers are found there in cases of oral cancer. In some cases of leukoplakia tumor marker like PCNA, Ki-67 are found which can be value predicting lesion behavior.

Microsatellite Markers

It is one of sensitive method for studying clonal changes in tumors and premalignant lesion. This requires small quantities of DNA. It is done by polymerase chain based Microsatellite analysis.

In oral premalignant lesion loss of heterozygosity is seen.

Immunofluorescence Procedure

Fluorescent dyes such as fluorescein isothiocyanate (FITC) and rhodamine can be chemically linked (conjugated) with antibody globulin without destroying the specificity of the antibody. Such fluorescent labeled antibodies used to detect specific antigen-antibody reaction can be used to locate either antigens or antibodies of known specificity in tissue sections. When tissue sections labeled in this fashion are illuminated with ultraviolet light in an ultraviolet microscope, specific labeled tissue component can be identified by their bright apple green fluorescence against a dark or counter stained background. The technique is used to identify a number of tissue structures and abnormal deposits of antibody globulin and other macromolecules as well as bacteria and viruses in infected tissues and smears.

It is carried out in the following three ways.

Direct Immunofluorescence

- *Application of fluorescent labeled antiserum*—fluorescent labeled antiserum directed against a particular tissue component is applied directly to a thin, unfixed smear or tissue section mounted on a slide.
- *Incubation of slide*—the slide is incubated at 37°C to allow the antigen and the labeled antibody to react.
- *Washing of slide in buffered normal saline*—following incubation, the slide is washed in buffered normal saline to remove un-reacted labeled antibody.
- *Examination under ultraviolet microscope*—the slide is examined in ultraviolet microscope.

Indirect Immunofluorescence

- *Application of unlabeled specific antiserum and FITC conjugated anti-globulin antiserum*—it is directed against a particular tissue component. Applied directly to the smear or tissue section, allowed to react and followed by a FITC conjugated anti-globulin antiserum.
- *Examination under ultraviolet microscope*—following incubation and washing to remove unreacted reagent, the slide is examined in the ultraviolet microscope.
- *Advantages*
 - *Brighter fluorescence*—the fluorescence is brighter because several fluorescent anti-globulin molecules bind onto each of the antibody molecules in the specific antiserum (Fig. 8-8).
 - *Cost effective*—because the process of conjugation is lengthy, there is considerable cost saving and versatility to the indirect technique, which requires only one labelled antiserum.
 - *More staining*—staining of more than one tissue component per slide can also be accomplished.

Fig. 8-8: Positive immunofluorescence in case of HSV infection.

Sandwich Technique of Immunofluorescence

- *Why called sandwich*—the name sandwich technique refers to the fact that antigen is sandwiched between two layers of the same specific antibody, one labeled and one not.
- *Reaction of solution of antigen with antibody*—appropriately fixed tissue sections are reacted with a solution of the antigen for which specific antibody is to be identified in the section.
- *Application of FITC labeled antiserum*—following incubation and washing, FITC labeled antiserum with the same specificity as that to be identified in the section, is applied to the section. The labeled antiserum again identifies the location of the tissue component.

Caries Activity Tests (Fig. 8-9)

Caries activity can be defined as the occurrence and rate at which teeth are destroyed by the acid produced by plaque bacteria or it can also be defined as the sum total of new carious lesions and the enlargement of existing carious cavities during the given time.

Uses

- *Preventive measures*—to determine the need and extent of preventive measures.
- *Success of therapeutic measure*—to determine the success of therapeutic measures.
- *Diet counseling and oral hygiene procedure*—to motivate and monitor the effect of education programs related to diet counseling and oral hygiene procedures.
- *Identification of high risk group*—to identify high risk groups and individuals.

Lactobacillus Count Test

It was introduced by Hadley in 1933. It estimates the number of bacteria in the patient's saliva by counting the number

of colonies appearing on tomato Peptone Agar or L.B.B. Agar.

Although it is quick and easy, the results are not available for several days and counting colonies is a tedious and complex process.

Technique

- *Collection of saliva*—stimulated saliva is collected before breakfast by chewing paraffin.
- *Spreading on agar plate*—this is shaken and 1:10 and 1:100 dilutions are spread on the surface of agar plate.
- *Incubation*—these are incubated at 37°C for a period of 3-4 days. The number of colonies is then counted in a Quebec counter.
- *Results*—the count expressed as the average number of colonies per milliliter of the original saliva sample.

Interpretation

- *Immune*—if the count is less than 10^3 then the patient is immune.
- *Slight*—if the count is between 10^3 —5000, caries activity is slight.
- *Medium*—if the count is between 5000— 10^4 , caries activity is medium.
- *High*—if it is more than 10^4 then caries activity is high.

Snyder Test

This test measures the ability of microorganisms in saliva responsible for formation of acids from carbohydrate media.

Technique

- *Collection of saliva*—the saliva sample is collected in a manner similar to the Lactobacillus colony count test.
- *Snyder media*—the media contains bactopectone (20 gm), dextrose (20 gm), sodium chloride (5 gm), agar (16 gm) and bromocresol green (0.02 gm).
- *Mixing of media with saliva*—then 0.2 cc of saliva is pipette into the media which is incubated at 37°C for a period of 72 hours.
- *Results*—bromocresol green, being an indicator, changes the color from blue green to yellow in the range of pH of 5.4-3.8. The color change is then correlated with the caries activity.

Interpretation

- *High*—if color changes in 24 hours, caries activity are high.
- *Medium*—if the color changes in 48 hours, it is medium.
- *Slight*—if color changes in 72 hours, it is slight.
- *Immune*—if there are no color change patient is immune to caries.

Alban's Test

It is a modification of Snyder's test. It uses less quantity of agar i.e. 5 ml per tube. Because of its simplicity and its low cost it is recommended for all patients prone to caries.

The main feature of Alban's test is the use of a softer medium that permits the diffusion of saliva and acids without the necessity of melting the medium and use of a simpler sampling procedure in which the patient expectorates directly into the tubes that contain the medium.

Technique

- *Preparation of Alban medium*—60 gm of Snyder test agar is placed in 1 liter of water and the suspension is brought to boil over a low flame or a hot plate at medium heat (excessive heating should be avoided to prevent scorching of medium). When thoroughly melted, agar is distributed, using about 5 ml per tube. The tube should be autoclaved for 15 minutes, allowed to cool and stored in a refrigerator.
- *Mixing and incubation of saliva with Alban medium*—two tubes of Alban medium are taken from the refrigerator and saliva is drooled directly into the tubes and tubes are incubated for 4 days at 37° Celsius.
- *Results*—the tubes are observed daily for change in color. The color change is noted from bluish green to yellow and the depth to which change has occurred is noted.

Interpretation

- *Negative*—no color changes.
- + beginning of color change (from top of the medium towards bottom).
- ++ one-half color changes.
- +++ three-fourth color changes.
- ++++ total color change.

Streptococcus Mutans Level in Saliva

Saliva samples are obtained by using tongue blades (after air drying the tooth for plaque samples). These are then incubated on M.S.B. agar (Mitis Salivarius Bacitracin Agar). The number of colonies is then used to estimate the caries activity and more than 10^5 colonies per ml of saliva is indicative of high caries activity.

Detection of mutans streptococci in dental plaque and stimulated saliva

Attach the strips to the cap and recap the vial

Incubation (48 hours)

Interpretation (screening strips)

Interpretation (site strips)

Buffer Capacity Test

Technique

- *Collection of saliva*—10 ml of stimulated saliva is collected under oil at least one hour after eating; 4 ml of this is measured into a beaker.
- *Adjusting pH of saliva to 7*—after collecting the pH meter, the pH of saliva is adjusted to 7.0 by addition of lactic acid or base at room temperature.
- *Results*—the level of lactic acid in the graduated cylinder is re-recorded. Lactic acid is then added to the sample until a pH of 6.0 is reached. The number of millimeter of lactic acid needed to reduce pH from 7.0 to 6.0 is a measure of buffer capacity of saliva.

Interpretation

- *Low buffer capacity*—saliva sample requiring less than 0.45 ml of standard hydrochloride acid to reduce the pH to 5 has low buffer capacity.
- *High buffering capacity*—saliva sample requiring 0.45 ml or more has high buffering capacity.

Fosdick Calcium Dissolution Test

Technique

- *Collection of saliva*—twenty five milliliters of gum stimulated saliva is collected.
- *Keeping powdered enamel with saliva*—part of this is analyzed for calcium content and the rest is placed in an eight inch sterile test tube with about 0.1 gm of powdered human enamel.
- *Shaking of tube*—the tube is sealed and shaken for four hours at body temperature after which, it is again analyzed for calcium content. If paraffin is used, a concentration of about 5% glucose is added.

Interpretation

- The amount of enamel dissolution increases as the caries activity increases which is indicated by an increase in the calcium content of saliva.

Dewar Test

Technique

- *Collection of plaque sample*—plaque samples are collected from the gingival third of buccal tooth surfaces and placed in Ringer's solution.
- *Mitis Salivarius agar plate*—the sample is shaken until homogenized. The plaque suspension is streaked across a Mitis-Salivarius agar plate.
- *Incubation*—after aerobic incubation at 37° C for 72 hours, the culture is examined under a low power microscope and the total colonies in 10 fields are recorded.

Interpretation

- This test is an attempt to semi-quantitatively screens the dental plaque for a specific group of caries causative organisms including streptococci.

Swab Test

The swab test involves sampling of the oral flora by swabbing the buccal surface of teeth and placing it in Snyder media. This is incubated for 48 hours and the pH changes are read and correlated with caries activity.

Reductase Test

This test measures the activity of salivary enzyme reductase.

Technique

- *Collection of saliva and mixing with diazoresorcinol*—saliva is collected and the sample is mixed with a diazo-resorcinol, which colors the saliva blue.
- *Results*—the change in color from blue to red is measured after 30 seconds and 15 minutes and this is taken as measure of caries activity.

Interpretation

- *Non-conductive*—if it remains blue after 15 minutes it is non-conductive.
- *Slightly conductive*—if it changes to orchid after 15 minutes, it is slightly conductive.
- *Moderately conductive*—if it changes to red after 15 minutes, moderately conductive.
- *Highly conductive*—if it changes immediately to red, it is highly conductive.
- *Extremely conductive*—if it changes to pink or white immediately, it is extremely conductive.

Hematological Investigation

Normal values are given in Table 8.1.

Collection of Blood Specimen

- *Capillary blood specimens*—these are convenient for office and chair side procedures. The specimen is obtained by pricking the patient's finger (an earlobe, ankle pad can also be used). Procedure is as follows
 - *Equipment*—jar of sponge soaked in 70% alcohol.
 - *Application of alcohol to patient finger*—the palmar surface of the patient's index finger or second finger is gently rubbed with sponge soaked in 70% alcohol. Excess alcohol is wiped off and the alcohol is allowed to evaporate.

- *Puncturing the finger with blood lancet*—the prepared area is rapidly punctured with a blood lancet taking care not to squeeze the finger (**Fig. 8-10**).
- *Collection of blood sample*—the patient's hand is at about the waist level and the first drop of the blood that wells up is wiped out with dry sponge. The next drop that appears allows to flow into a capillary tube or is collected on a glass slide.

Fig. 8-10: Collection of capillary blood specimen is done by finger pricking.

- *Venous blood specimen*—venous blood specimens are used for majority of tests that are to be performed in clinical diagnostic laboratory. Venipuncture is usually performed in antecubital vein (**Fig. 8-11**). Procedure is as follows:
 - *Equipment*—a 10 to 20 ml sterile disposable syringe with a 20-gauge needle or Vacutainer. Needle, adaptor and evacuated collection tubes, tourniquet or approximately 20 inch of soft tissue rubber tubing,

Fig. 8-11: Venous blood is taken by venipuncture method.

less than ½ inch in diameter. Jar of sponges soaked in 70% alcohol and jar of dry sponge.

- *Preparation of patient*—prepare the patient and equipment. Apply the tourniquet and select the vein to be punctured.
- *Preparation of puncture site*—prepare the puncture site with 70% alcohol and air dry.
- *Collection of blood*—insert the needle through the skin and into the vein. Aspirate blood into a syringe or Vacutainer tube and remove the tourniquet.
- *Maintenance of puncture site*—place dry cotton swab over the puncture site and withdraw the needle. Bring the patient's forearm back against his upper arm while he maintains finger pressure on the cotton at the puncture site with the other hand.
- *Delivery to laboratory*—specimen should be delivered to the laboratory within 1-2 hours in a tube which should be well sealed and protected from breaking.
- *Arterial blood specimen*—arterial blood specimen is obtained by puncturing the radial artery.

Total Erythrocyte Count

It gives the number of erythrocytes per cubic millimeter in circulating blood and also gives an indirect estimate of hemoglobin in blood. It is determined by hemocytometer.

Procedure

- *Office and chair side*—the test is performed manually under a microscope by direct counting of the number of cells in diluted sample of blood confined in a calibrated chamber of special glass microscope slide (hemocytometer technique).
- *Automated procedure*—the electronic counting of erythrocyte is usually carried out with equipment such as *coulter counter model* (Fig. 8-12). The sample of whole

Fig. 8-12: Hemocytometer is used to calculate RBC count.

blood is aspirated into the machine and automatically diluted with modified Eagle's solution before being drawn through three narrow chambers equipped with electrodes. As the cells pass through an aperture, their presence and dimensions are accurately recorded by a drop in voltage across the electrodes. The reading for three aperture tubes is obtained as average and an average RBC count is displayed and printed out by the machine.

Interpretation

- Earliest signs and symptoms of hematological disease affecting erythrocytes are anemia and polycythemia. It is reduced in some anemia and increased in polycythemia and dehydration.

Erythrocytes Indices

In evaluation of nature of anemia, assistance is obtained by calculating standard indices relating to the size of RBCs. By measuring these indices we can classify anemia as microcytic, macrocytic and normocytic and hypochromic and normochromic (Tables 8.1 and 8.2).

Types

- *MCH*—the hemoglobin content of erythrocyte is referred to as the mean corpuscular hemoglobin (MCH) expressed in picograms of hemoglobin per cell.
- *MCHC*—the concentration of hemoglobin in the erythrocyte is referred to as the mean corpuscular hemoglobin concentration (MCHC)
- *MCV*- average red cell volume referred to as the mean corpuscular volume (MCV) is expressed in cubic microns per cell.

Table 8-1: Different erythrocytes indices

Indices	Calculation
MCH	$\frac{\text{Hemoglobin concentration (g/dl)}}{\text{RBC in million/mm}^3} \times 10$
MCHC	$\frac{\text{Hemoglobin concentration (g/dl)}}{\text{Hematocrit}} \times 100$
MCV	$\frac{\text{Hematocrit}}{\text{RBC in million/mm}^3} \times 10$

Table 8.2: Different types of anemia and erythrocytes indices

Types of anemia	MCV	MCH	MCHC
Microcytic hypochromic	Decreased	Decreased	Decreased
Macrocytic normochromic	Increased	Increased	Normal
Normocytic normochromic	Normal	Normal	Normal

Hematocrit

It is a measure of volume percent of packed red blood cells in whole blood.

Indications

- *Anemia*—the classic signs and symptoms of anemia indicate for the measurement of the hematocrit value.
- *History of blood loss*—history of excessive blood loss, pallor of oral mucous membrane, palate, conjunctiva, nailbeds.
- *Evaluation of patient for general anesthesia*—To evaluate patient's ability to tolerate general anesthesia or oral surgical procedures.
- *Others*—unexplained syncope, excessive fatigue, glossitis and atrophy of lingual papillae, recurrent and persistent gingivitis and stomatitis.

Technique

- *Equipment*—2 heparinized microhematocrit capillary tubes. A box of matches and microhematocrit centrifuge equipped with reader and magnifier.
- *Collection of blood*—blood is obtained by a finger prick or venipuncture and is allowed to flow by capillary action into two microhematocrit tubes, until each is about $\frac{3}{4}$ th filled. The volume of blood should be free from air bubbles.
- *Sealing of tube*—the end of each tube away from the column of blood is sealed by melting the glass in the flame of a match or small gas jet without heating the blood.
- *Keeping tube in centrifuge*—the tubes are cooled and placed opposite to each other in the slots of the head of the centrifuge, with sealed ends pointing outward. The centrifuge head covers are closed and the centrifuge timer is set for 5 minutes.
- *Centrifugation*—the centrifuge is started and it accelerates to 12,500 rpm and stop automatically at the end of required time.
- *Results*—the centrifuge head covers are removed and with the aid of magnifying lens for greater accuracy, the hematocrit is read by means of scale incorporated in the head of the instrument.

Interpretation

- *Increase*—increase in the value indicates primary and secondary polycythemia and dehydration.
- *Decrease*—value is decreased in anemia.

Measurement of Hemoglobin Concentration

It is expressed in gm/dl. It is require to obtain information about circulating RBC's and the oxygen carrying capacity. It is also used for calculation of MCHC and MCH.

Technique

- *Photoelectric calorimeter*—the hemoglobin concentration is usually measured on anti-coagulated venous blood by reacting the sample with a reagent that converts the hemoglobin to stable colored product. The concentration of this colored compound is measured in photoelectric colorimeter in comparison with the standard.
- *Drabkin's method*—different methods used are Drabkin's technique in which hemoglobin is converted into the stable pigment cyanmethemoglobin. Drabkin's solution contains potassium cyanide and ferricyanide and sodium bicarbonate.
- *Other method*—other techniques used are Sahli's method (0.1 N hydrogen chloride), oxyhemoglobin method (0.1 sodium carbonate).

Interpretation

- *Increased*—it is increase in primary and secondary dehydration.
- *Decrease*—hemoglobin concentration decreased in anemia.

WBC Count

In the management of dental patients total WBC count is used as one of the index of presence of systemic infection and to rule out possibility of leukemia and malignant neutropenia (Table 8-3).

The total WBC count can be calculated manually with a hemocytometer or with an automated cell counter. To count WBCs in the presence of RBCs, RBCs are lysed by diluting the blood sample with dilute acetic acid or equivalent reagent supplied by the manufacture of the automated equipment leaving the WBCs intact.

Table 8-3: Interpretation of WBC count

Increased in (leukocytosis)	Decreased in (leukopenia)
• Infection –acute and chronic • Leukemia • Polycythemia • Trauma • Exercise, fear and pain • After general anesthesia	• Aplastic anemia • Influenza, measles and respiratory tract infection • Catarrhal jaundice • Early leukemia • Depression of bone marrow due to certain drugs • Drug and chemical toxicity, shock

Differential Leukocyte Count

As the WBCs in circulating blood are of several types and of varied origin, the total leukocyte count is of limited use without a differential count of the various types of cells present. Five types of WBCs are commonly present in circulating blood. They are neutrophils, lymphocytes, monocytes, basophils and eosinophils.

Technique

- **Staining**—it is performed on air dried smear of blood stained with Wright's or other Romanovsky-type stain to differentiate types of WBCs from each other. Nowadays various instruments are used to calculate DLC count (**Fig. 8-13**)
- **Relative percentage**—the relative percentage of each type of WBC is obtained by counting a minimum of 100 to 200 cells per slide and the fields counted are selected in such a way that the effect of uneven distribution of WBCs in the smear is overcome.

Fig. 8-13: DLC count is calculated by instrument.

Interpretation

It is discussed in Table 8-4.

Platelets

Platelets are small $2\ \mu$ to $5\ \mu$ particles released from the cytoplasm of large multinucleated cells (megakaryocytes) located in the red bone marrow.

Because of the platelet's small size and tendency to aggregate, (an important phenomenon related to their function in the hemostatic mechanism) platelet counts on peripheral blood smear have a large technical error.

Counts are performed manually using a special hemocytometer counting chamber and a phase contrast microscope or by means of an automated cell counter such as the Technicon Autoanalyzer. Interpretation of platelet is discussed in Table 8.5.

Bleeding Time

It measures the time required for hemostatic plug to form. Lack of any clotting factor and platelet abnormalities may increase the bleeding time. It is a useful screening test in patients with a history of prolonged bleeding following previous surgery. It should be carried out in patients in whom certain symptoms are with strongly suggestive of bleeding disorders.

Table 8-4: Interpretation of different types of WBCs in disease

Increased in	Decreased in
Neutrophils	
• Pregnancy, exercise • Infection, inflammation • Neoplasm, severe hemorrhage • Hemolysis and erythroblastosis fetalis • Intoxication by drugs and poisons like corticosteroids	• Aplastic anemia • Cyclic neutropenia • Malignant neutropenia • Drug induced myelosuppression • Early leukemia
Lymphocytes	
• Lymphocytic leukemia • Mumps—German measles • Whooping cough • Chronic infection • Convalescence from acute infection	• Aplastic anemia • Myelogenous anemia
Monocytes	
• Hodgkin disease • Monocytic anemia • Malaria—kala-azar • Sub-acute bacterial endocarditis • Tuberculosis	• Aplastic anemia • Acute leukemia
Eosinophils	
• Parasitic infection • Allergic disease • Drug reaction dermatoses like pemphigus, pemphigoid, atrophic dermatitis • Scarlet fever	• Immune defect • Acute stress • Injection of adreno-corticotrophic hormone • Typhoid fever • Aplastic anemia
Basophils	
• Chronic myelogenous leukemia • Polycythemia • Myelofibrosis	

Table 8.5: Interpretation of platelets

Increased in (Thrombocytosis)	Decreased in (Thrombocytopenia)
• Chronic myelocytic leukemia • Polycythemia vera • Hemolytic anemia • Trauma	• Thrombocytopenic purpura • Immune reaction • Transfusion • Aplastic anemia

Technique Equipment

- **Equipment**—sphygmomanometer, cuff, jar of sponges soaked in 70% alcohol and jar of dry sponges, blood lancet, 3 to 4 pieces of filter paper about 1 inch square, stop watch (**Fig. 8-14**).
- **Patient position**—the patient is seated comfortably with his arm supported on the chair arm or his own thigh.
- **Application of cuff to patient**—the sphygmomanometer cuff is applied to the patient's upper arm and inflated to 40 mm pressure.

- *Scrubbing area with alcohol swab*—an area on the palmar (inner) surface of the forearm about halfway between elbow and wrist that is free of superficial veins, is located and prepared by scrubbing with an alcohol soaked swab.
- *Punctured with blood lancet*—after the area is air dried, the skin of the prepared area is tensed and punctured with a blood lancet cutting deep enough such that the hit is firmly pressed against the skin of the arm.
- *Results*—the lancet is immediately removed and the time noted on a watch equipped with a seconds hand. Every 30 seconds by the watch, an edge of filter paper is touched against the drop of blood that wells up. The length of time until the bleeding ceases is the bleeding time in minutes.
- *Cleaning the area*—the area is finally cleaned with a swab slightly moistened in 70% alcohol.

Fig. 8-14: Filter paper, blood lancet are used to calculate bleeding time.

Interpretation

- *An abnormal bleeding time*—it is usually the result of abnormalities in the structure or ability of the capillary blood vessels to contract or abnormalities in the number or functional integrity of the platelets.
- *Contributing factors*—a bleeding time of 5 minutes does not mean that a patient will stop bleeding from any type of wound in 5 minutes. The time for bleeding to stop is related to the way in which the wound is produced, the caliber of the vessels involved in the hemorrhage, the amount to tissue damage adjacent to the wound and systemic factors such as blood pressure and individual response to the type of anesthesia.

Capillary Fragility Test (Tourniquet Test and Rumpel Leede Test)

It is the test of the ability of superficial capillaries of the skin of the forearm and hand to withstand an increased intraluminal pressure and a certain degree of hypoxia. It is

done by occluding veins of the upper arm with a blood pressure cuff for five minutes.

Indications

- *Bleeding abnormalities*—it is used to screen for bleeding abnormalities especially where there is suspicion of platelet disorders.
- *Petechiae in oral cavity*—the discovery of petechiae in the oral cavity or on the skin is the most common indication for the capillary fragility test; especially where the petechiae are confined to the oral cavity and could also conceivably have resulted from local trauma or denture irritation.
- *Scurvy*—in dental practice, it is used as a screening test for scurvy, which is an etiological factor in periodontal disease.

Technique

- *Equipment*—sphygmomanometer and cuff, microscope slide.
- *Patient position*—the patient is seated with one arm supported on the chair arm or thigh.
- *Instruction to patient*—the dentist should explain the patient that his blood pressure will be taken and the cuff will be left on a little longer than the patient may be used to. He should be further explained that the procedure may make the patient's arm a little numb and even painful, but that discomfort will quickly disappear once the cuff is removed.
- *Examination of hand of patient*—during this time, the dentist examines the patient's forearms and hands for any petechiae and records their location with an ink spot. The blood in a petechial hemorrhage lies extravascularly and should not disappear upon pressure with the surface of a glass microscope slide.
- *Application of sphygmomanometer*—the sphygmomanometer is applied customarily and the patient's systolic and diastolic arterial blood pressure is recorded.
- *Inflation of cuff*—the pressure in the cuff is reduced to zero and the cuff is reinflated to a point halfway between systolic and diastolic pressure. This pressure is maintained for 5 minutes during which the forearm and hands are examined for development of new petechiae. The patient should not be moved vigorously while the cuff is in place because movement will increase anaerobic muscular glycolysis, lactate accumulation and thus result in pain.
- *Results*—after 5 minutes, the cuff is removed and the patient is allowed to exercise his arm to restore the circulation in the arm. The blood vessels of normal individuals will withstand these conditions and

petechial hemorrhages will not appear on the forearm and hand from rupture of superficial capillaries.

- **Positive test**—if any unequivocal petechiae develop distal to the cuff (toward the hand) after cuff has been applied, the test is recorded as positive (**Fig. 8-15**).
- **Negative test**—if only one or two petechiae are seen or if those seen are not convincing in their appearance, a negative test is recorded; retesting is done if required by investigating dentist.

Fig. 8-15: Appearance of petechiae on hand after tourniquet test.

Clotting Time

Procedure

- **Feeling of blood in dry tubes**—one millimeter of venous blood is placed in each of the four dry tubes of standard size, maintained in a water bath.
- **Tilting of tube**—the first tube is tilted at 30 seconds interval, until the blood no longer flow. The next tube it tilted until clotting occurs, after which the third and fourth tubes are similarly treated.
- **Results**—the average time between venipuncture and clotting in the last three tubes is expressed in minutes as the clotting time. The normal range is 10 to 25 minutes.

Interpretation

- **Increases**—it is prolonged in diseases affecting stage II and stage IV of coagulation. It is also increased in cirrhosis, hemophilia A and B, factor XI deficiency, hypofibrinogenemia and heparin and dicumarol anticoagulant therapy.

Erythrocyte Sedimentation Rate (ESR)

It is a measure of the rate at which RBCs sediment in a tube of plasma. The test is helpful in following the progress of some chronic infections (tuberculosis and osteomyelitis)

as well as diseases characterized by altered globulins such as the collagen diseases, nephritis, rheumatic fever and dysproteinemias.

Technique

- **Mechanism**—the rate is accelerated when there are changes in the physicochemical properties of plasma or the red cell surface or when the changes in plasma protein cause the RBCs to aggregate.
- **Westergren method**—in the Westergren method, a graduated sedimentation tube is filled with oxalated blood and placed in an absolutely vertical position (**Fig. 8-16**).
- **Results**—the erythrocyte level is read at 10 minutes intervals and at the end of an hour.

Fig. 8-16: ESR is calculated by Westergren method.

Hematological Investigation not so Frequently Required in Dental Office

- **Partial thromboplastin time**—it is the time, in seconds, that is required for a clot to form in a sample of oxalated plasma, to which a partial thromboplastin reagent and calcium chloride is added.
- **Prothrombin time**—it is the time in seconds that is required for fibrin threads to form in citrated or oxalated plasma, where known amount of tissue thromboplastin and calcium is added. Since last two reagents are present in excess, any delay in clotting in this test is suggestive of an abnormality of the prothrombin complex or a very severe fibrinogen deficiency.
- **Schilling test**—several types of megaloblastic macrocytic anemias of different etiologies are caused by vitamin B₁₂ deficiency. Schilling test is a measurement of patient's

ability to absorb orally administered radioactive vitamin B₁₂ labeled with ⁶⁰Co. Following oral administration of the radioactive vitamin B₁₂, unlabeled vitamin is given intramuscularly, as a flushing dose to induce urinary excretion of the labeled vitamin, which is measured in a 24 hour urine specimen. Patients with pernicious anemia (who are unable to absorb orally administered vitamin B₁₂) excrete less than 5% of the orally administered dose in comparison with excretion of 8 to 25% by normal individuals.

- *Serum iron and total iron binding capacity*—iron deficiency is the most common cause of anemia; however anemia occurs only after depletion of iron stores and iron deficiency may exist for some time before the appearance of anemia. Iron deficiency is usually detected on the basis of the amount of iron bound to transferrin in the plasma (serum iron) and the total amount of iron that can be bound to the plasma transferrin *in vitro* (total iron binding capacity or TIBC).
- *Bone marrow aspiration*—detailed evaluation of patients with anemia, leukemia, multiple myeloma, metastatic malignancy and other space occupying lesions frequently involves study of the immature erythropoietic and leukopoietic cells of the bone marrow. This is accomplished by aspiration of red bone marrow cells through a large bore needle inserted through a trochar into the iliac crest or sternal marrow space. The aspirate is then smeared thinly on a glass slide or coverslip, stained with Wright's stain and examined in the same ways as a smear of capillary or venous blood.
- *Bone marrow biopsy*—bone marrow biopsy is also used where an indication of the spatial relationship and degree of hyperplasia or hypoplasia of the cellular element in the marrow is needed.
- *Platelet survival time*—it is measured in thrombocytopenic purpura and other diseases in which rapid destruction of platelet occurs. A sample of autologous or isologous platelets labeled with radioactive ⁵¹Cr is added to a sample of patients blood and re-injected intravenously. The amount of radioactivity is then measured in blood samples taken at intervals over the next few days, depending on the design of the experiment. The normal platelet survival time (time required for the circulating radioactivity to drop to 10% of its peak value after injection of ⁵¹Cr labeled platelet) is between 8 to 9 days.

Blood Chemistry

Detection of Diabetes Mellitus

Diabetes mellitus is a disease of insidious onset that is not infrequently complicated by serious tissue changes leading

to permanent cardiovascular, renal, cerebral and optic damage.

Importance of Detection of Diabetes Mellitus in Dentistry

- *Periodontal therapy*—the response of diabetic patients to periodontal therapy may be much less satisfactory than non-diabetic, under similar conditions.
- *Healing of oral tissue*—the healing of oral tissues following surgery in diabetics is slower. Complication like tissue necrosis and secondary infections may occur in diabetic patient.
- *Oral disease*—certain oral diseases are predisposed to occur in association with diabetes mellitus (e.g. thrush, denture sore mouth).
- *Oral infection*—the systemic effects of acute localized oral infections may be much greater in a diabetic than in a non-diabetic.

Indications

- *Evaluation of patient suspected of diabetes mellitus*—for evaluation of a patient suspected of having diabetes mellitus. Its presence should be suspected whenever any of the following are found: history of weight loss in the presence of adequate diet, history of excessive thirst and attendant excessive and frequent urination, history of repeated episodes of boils, skin infections and periodontal abscesses and presence of severe periodontitis with excessive bone loss.
- *Screening test*—as a screening test for diabetes mellitus, where the dentist suspects the occurrence of disease in the absence of characteristic signs and symptoms.
- *Family history*—testing of the patient with a family history of diabetes.
- *Known diabetes patient*—as a measure of degree of control of disease in a patient who is known to be a diabetic but who is not under regular medical care and is unwilling to accept referral to a physician for reevaluation of the disease.

Types

- *Urine glucose estimation*—many diabetics excrete glucose in their urine, testing the urine with commercial available reagent strips (Tes-Tape, Clinistix, Chemstrip) is the most convenient screening method of diabetes (Fig. 8-17). But in patient with mild diabetes urine may not exhibit glycosuria. False positive urine sugar tests also occur in individuals with renal glycosuria.
- *Blood glucose estimation*—this is most accurate method for detection of diabetes mellitus. Three schedules for determination of blood glucose concentration are used:

- *Fasting blood glucose*—determination of fasting blood glucose is frequently used as a screening test for hyperglycemia in hospitalized patients. On an outpatient basis, however, maintenance of the fasting state from the evening meal until the next morning is difficult to ensure and may lead to a degree of hypoglycemia that an outpatient cannot tolerate without fainting.
- *Two hours postprandial blood glucose*—determination of the blood glucose two hours after a meal containing 75 gm of carbohydrate (2-hours postprandial blood glucose) is a more sensitive measurement of the hyperglycemia associated with diabetes. Both fasting and 2-hour postprandial blood glucose measurement can be carried out on capillary blood using the Dextrostix, Visidex, or Chemstrip reagent strip. Due to its convenience, simplicity and sensitivity, this test is recommended as the best screening procedure for a dentist to use if he suspects that a patient may be a diabetic and feels that he must explore the problems further by himself prior to medical referral.
- *Oral glucose tolerance test*—glucose tolerance test is one of the procedures used for the definitive diagnosis of diabetes mellitus. It is performed on series of blood samples in a laboratory and is used to confirm the diagnosis of a diabetic patient who does not exhibit constantly elevated fasting blood glucose.
- *Equipment*—blood lancet, jar of sponges soaked in 70% alcohol and jar of dry sponges. Dextrostix, Visidex, or Chemstrip bG reagent strip, wash bottle, urine jar, reagent strip to test for glycosuria.
- *Collection of blood sample*—blood sample is taken with the help blood lancet.
- *Application of reagent strip to blood*—the first drop that wells up is wiped away and the next few drops are freely applied to the entire reagent area on the printed side of blood glucose reagent strip. The blood is allowed to permeate and react with the reagents contained in the strip for exactly 1 minute.
- *Removal of blood from strip*—the blood is then washed from the strip as completely as possible with a sharp stream of water from the wash bottle or faucet.
- *Results*—the test area of the strip is immediately compared with the color chart on the side of the bottle, matching the strip; if the color obtained is intermediate between two color blocks, the result is inappropriate, otherwise, the value for a matching block is read directly.
- *Urine glucose*—the patient is requested to void a sample of urine in the specimen jar provided. This is tested for the presence of glucose by using the appropriate reagent strip.
- *Blood glucose*—the normal range of blood glucose in the fasting state is approximately 70 to 110 mg/dl. The concentration rises to about 160 mg/dl following a meal in normal persons but returns to the fasting level within 2 hours. In diabetics of moderate severity, fasting levels may reach 200 mg/dl, postprandial levels are greater than this and may persist for longer than 2 hours after meals. The diagnosis of diabetes mellitus should be made only after a complete medical history, physical examination and appropriate laboratory tests carried out by a physician. If the 2 hour postprandial blood glucose is above 140mg/dl, the patient is clearly metabolizing glucose in an abnormal fashion.
- *Urine glucose*—when the blood level of glucose exceeds 160 to 180 mg/dl, the normal renal threshold for glucose is exceeded and so glucose will appear in urine which will give a positive test for glucose. The renal threshold for glucose may become elevated as a result of kidney disease and this phenomenon is an important cause of false negative tests for glucosuria in diabetes mellitus and number of other diseases which are associated with hyperglycemia.

Fig. 8-17: Glucometer used for detection of blood glucose.

Technique

Two hour postprandial blood glucose

- *Diet instructions*—patient may take serving of 1 fruit juice plus 1 bowl of cereals with 2 tea spoonful of sugar plus 1 cup of milk plus coffee or tea with sugar plus anything he desires at breakfast at 8 am. If the patient is to be retested in the afternoon, he may eat 1 sandwich plus 1 piece of cake or pie plus coffee or tea with sugar or milk plus anything else he wishes for lunch at 1 pm.

Oral glucose tolerance test

- *Significance*—for many years, glucose tolerance test has been accepted procedure for making a definitive diagnosis of diabetes mellitus and for distinguishing diabetes from other causes of hyperglycemia such as hyperthyroidism. Elevated levels for fasting plasma

glucose, in this context include any concentrations equal to or greater than 140 mg/dl. The OGTT should be administered only to healthy ambulatory patients who are known to be taking no drugs that interfere with the laboratory determination of glucose.

- *Oral glucose challenge*—the oral glucose challenge traditionally used in the glucose tolerance test has varied from 50 to 100 gm, administered either as a glucose solution, and commercially prepared carbohydrate load or a meal equivalent to this glucose dose.
- *Subject preparation*—the test should be performed in morning, after at least 3 days of unrestricted diet (greater than 150 gm of carbohydrate daily) and physical activity. The subject is made to fast for at least 10 hours but not more than 16 hours before the test (water is permitted during this period). The subject should remain seated and should not smoke throughout the 2 hours of test period.
- *Fasting blood sample*—a fasting blood sample should be collected.
- *Sample after oral glucose challenge*—subject has to drink the glucose dose in a concentration; no greater than 25 gm/dl of flavored water, in about 5 minutes. Zero time is the beginning of the drink and blood samples are then collected at 30 minutes interval for 2 hours (a total of five blood samples per test).
- *Storage of sample*—capillary blood samples are preferred. Blood sample should be collected in a tube containing sodium fluoride to inhibit glycolysis and potassium oxalate to prevent clotting. The sample should be centrifuged and separated within 4 hours and plasma freezes unless glucose levels are to be determined immediately.

Blood Chemistry Investigation not so Frequently Carried Out in Dental Office

- *Serum calcium, phosphorus*—it is indicated when you suspect Paget's disease, fibrous dysplasia, primary and secondary hyperparathyroidism, osteoporosis, multiple myeloma, osteogenic sarcoma or metastatic malignancy. It acts as initial screening procedures. The concentration of calcium in serum and body fluids tends to vary inversely with the concentration of inorganic phosphorus (2 mg/dl to 5 mg/dl). The product of serum calcium concentration and serum phosphorus concentration is constant at about 30 to 40 in normal adults, but may be as high as 50 to 60 in growing children. At serum calcium below 7 mg/dl (such as may occur in patients with hypoparathyroidism), signs of tetany (neuromuscular excitability, positive Chvostek's sign) appear.
- *Serum alkaline phosphatase*—alkaline phosphatase occurs in many tissues of the body, but notably in osteoblasts.

Increase in serum concentration of this enzyme is seen primarily as a result of increased osteoblastic activity but also in association with obstructive liver diseases and a variety of miscellaneous conditions such as malignancy or abscess of the liver, amyloid disease, leukemia and sarcoidosis. It should be remembered that increased osteoblastic activity is not restricted to sclerosing (radiopaque) bone lesions but may be quite high in lytic (radiolucent) bone lesions also, as a result of remodeling of the surrounding bone that accompanies a lytic lesion.

- *Serum uric acid*—concentration usually lies in the range of 4 mg/dl to 8.5 mg/dl for males and 2.8 mg/dl to 7.5 mg/dl for females. Uric acid is a metabolic end product of nucleoprotein metabolism derived from the purine molecule. Increase occurs in acute phases of diseases such as leukemia, lymphomas, anemia or lobar pneumonia; in which there is rapid destruction of large number of DNA rich leukocytes. Measurement of uric acid is important in the evaluation of intrinsic disease of temporomandibular joint, particularly when nodules consistent with gouty tophi are noted about the face or ears. In gout, values of 8 mg/dl to 15 mg/dl for serum uric acid are usually observed.
- *Serum albumin and globulin*—the concentrations of serum albumin and globulin, as well as the total serum protein are routinely measured as part of the standard blood chemistry profile.
- *Serum protein electrophoresis*—it is useful screening test in patients with suspected oral lesions of multiple myeloma or systemic lupus erythematosus. It is usually indicated when radiolucent defect detected in the jaw. In serum protein electrophoresis a small volume of serum is subjected to a low voltage electric current causing the proteins of the serum to migrate at different rates. When the serum proteins are distributed across a piece of filter paper or a block of starch or other gelled supporting medium, they may be separated and stained as relatively distinct bands and the concentration of each serum protein component calculated.
- *Serum bilirubin*—jaundice can be recognized by examination of the color of skin, oral mucous membrane and sclera of eyes. It may indicate the presence of hepatitis which can constitute an infectious hazard for a dentist and his patients. Jaundice is usually not evident until total serum bilirubin (derived from red blood cells broken down at the end of their normal 120 days life-span) rises from a normal range of 0.1 mg/dl to 0.8 mg/dl to above 2 mg/dl to 3 mg/dl.
- *Thyroid function test*—it is currently measured either by uptake of a radioisotope by the thyroid gland or by direct measurement of thyroid hormones, triiodothyronine (T_3) and thyroxine (T_4) in serum. T_4 levels in serum are

Table 8-6: Chart of normal values

Test	Normal value
Hemoglobin	Males—14- 17.4 gm/dl Females—12.3 to 15.3 gm/dl
Red blood cell	Males—4.5 –5.9 million/mm ³ Females—4.5 –5.1 million/mm ³
WBC	4000-11000 / mm ³
Platelet count	1,50,000 –4,50,000 /mm ³
Hematocrit	At birth—54 Adult males—42-50% Adult females—36-45%
Red cell indices MCV MCH MCHC	80-96 cu micron 27-31 pg 32-36 gm/dl
ESR	Males (under 50) <15mm/hr Males (over 50) < 20 mm /hr Females (under 50) < 20 mm/hr Females (over 50) < 30 mm / hr
Differential WBC count (range) Neutrophils—50-77 % Eosinophils—0-4 % Basophils—0-2 %	Absolute value 2500-7000/ul 50-500/ul 0-100/ul
Lymphocytes—20-47% Monocytes—0-9 %	1000-4000/ul 200-800/ul
Reticulocyte count	0.5-2.5 %
Bleeding time	1-6 minutes
Clotting time (capillary) (Lee and White)	3-5 minutes 4-10 minutes
Clot retraction	½ of original mass in 1 hr
Prothrombin time	12-15 seconds
Thrombin time	10-12 seconds
Plasma fibrinogen	150-400 mg/dl
PTTK (kaolin activation)	30-35 seconds

Table 8-7: Normal blood chemistry value

Test	Material	Normal value
Amylase	Serum	0.8 to 3.2 U/L
Bilirubin (total)	Serum	0.1 to 1 mg /dl
Cholesterol (total)	Serum	150-250 mg/dl
Uric acid	Serum	Males—3.5 to 7.5 mg/dl Females—2.5 to 6.6 mg/dl
Calcium	Serum	8.8-10.5 mg/dl
Chloride	Serum	98-108 mEq/L
Sodium	Serum	135-148 mEq/L
Potassium	Serum	3.5-5.5 mmol/l
Phosphorus	Serum	2.5-4.5 mg%
SgPT	Serum	5.40 IU/L
SgOT	Serum	5.40 IU/L
Creatinine	Serum	Males—0.7 to 1.4 mg/dl Females—0.6 to 1.3 mg/dl
Folate	Serum Erythrocyte	5-25 mg/ml 166-640 mg/ml
Glucose	Serum (fasting) Whole blood Post prandial	70-110 mg/dl 60-90 mg/dl less than 140 mg/dl
Iron (total)	Serum	60-150 µg/dl
Iron binding capacity	Serum	250-400 µg/dl
Iron saturation	Serum	20-55%
Phosphatase acid	Serum	0.2 to 1.8 U/L
Alkaline phosphatase	Serum	25-100 U/L
Protein total	Serum	6-7.8 gm/dl
Albumin		3.2-4.5 gm/dl
Globulin		2.3-3.5mg/dl
Triglyceride	Serum	4-150 mg/dl
Urea nitrogen	Serum	8-18 mg/dl
Magnesium	Serum	1.3 to 2.1 mEq/L
Thyroid hormones Thyroxin T ₄ T ₃	Serum (RIA)	4.1 to 11.3 µg/dl 5 ng/dl 0.6 ng/dl

Table 8-8: Comparison of calcium, phosphorus and alkaline phosphatase levels in common disorders of bone and calcium metabolism

Disease	Serum calcium	Serum phosphorus	Serum alkaline phosphatase
Normal	8.8 to 10.5 mg /dl of blood	2 to 5 mg / dl of blood	1 to 4 units/dl of blood in adult (Bodansky)
Rickets	Usually normal except in tetany	Decreased	Increased 20 to 40 X normal
Osteomalacia	Decreased	Decreased	Little if any changes
Hyperparathyroidism	Marked increased	Usually decreased	Increased 2 to 50 X normal
Paget's disease	Usually normal	Usually normal	Occasionally elevated
Osteogenesis imperfecta	Usually normal	Usually normal	Usually normal
Solitary bone cysts	Normal	Normal	Normal
Metastatic osseous neoplasms	May be elevated	Normal	Normal or may be slightly elevated
Tetany	7 mg/dl blood or less	Normal or elevated	Normal

Fig. 8-18: Intraoral periapical radiograph is backbone of dentistry.

currently measured either by protein displacement technique or by radioimmunoassay (RIA). Serum T_4 levels, as measured in this way depend on the availability of thyroxin-binding sites on plasma proteins. When estrogen levels increase, thyroxin binding sites increase in serum and serum T_4 levels increase.

Radiological Investigations

Intraoral Projection

It is the backbone of dental radiography.

- *Intraoral periapical*—it shows all the teeth including surrounding bone and mainly the periapical area (Fig. 8-18).
- *Occlusal*—it shows more areas of teeth and bone than seen in an IOPA radiograph.
- *Bite wing*—it only shows crowns of teeth and adjacent alveolar crests.

Fig. 8-19: Extraoral projection (Water's view) is also indicated in maxillary sinus disorders.

Figs 8-20A and B: Specialized technique like OPG (A) and Computed tomography (B) is also act as valuable aid in making diagnosis of the lesion in oral cavity.

Extraoral Projection

There are many extraoral views which are useful in dental radiography. They are posteroanterior skull, lateral oblique body and ramus of mandible, lateral skull, reverse Towne's, TMJ radiography and Submentovertex view (**Fig. 8-19**).

Special Radiological Examination

Specialized radiographic examination like cephalometric, sialography, OPG, ultrasound, MRI, computed tomography, digital radiography, and radionuclide imaging is carried out (**Fig. 8-20**).

Classification

Developmental Tooth Alteration

Size of Teeth

- Microdontia
- Macrodontia

Shape of Teeth

- Gemination
- Twinning
- Fusion
- Concrescence
- Talon cusp
- Dilaceration
- Dens in dente
- Dens evaginatus
- Hypercementosis
- Supernumerary roots
- Paramolar tubercle or Bolk cusp
- Enamel pearl or droplet or nodule
- Globodontia
- Mulberry molar
- Moon's molar
- Hutchison incisor
- Carabelli cusp
- Shovel shaped incisor

Number of Teeth

- Anodontia
- Supernumerary teeth
- Pre-deciduous dentition

Structure of Teeth

- Amelogenesis imperfecta
- Dentinogenesis imperfecta

- Dentin dysplasia
- Regional odontodysplasia
- Dentin hypocalcification

Environmental Tooth Alteration

Environmental Structure Defect

- Enamel hypoplasia

Disturbance of Eruption

- Premature eruption
- Delayed eruption
- Impacted teeth
- Embedded teeth
- Ankylosis of teeth
- Transposition
- Eruption sequestration
- Ectopic eruption
- Premature exfoliation

Postdevelopmental Tooth Loss

- Attrition
- Abrasion
- Erosion
- Internal resorption
- External resorption

Discoloration of Teeth

- Bacterial stain
- Tobacco stain
- Restorative material
- Medication
- Chlorhexidine stain
- Intrinsic stain
- Erythropoietic porphyria

- Alkaptonuria
- Erythroblastosis fetalis
- Hyperbilirubinemia
- Trauma
- Lepromatous leprosy
- Tetracycline stain

Pulp Disease

- Pulp calcification
- Necrosis of pulp

3

Developmental Disturbances of Teeth

Size of Teeth

Microdontia

It refers to teeth that are smaller than normal. Microdontia is usually transmitted as an autosomal dominant with incomplete penetrance.

Types

- *True generalized*—all the teeth are smaller than normal. It occurs in pituitary dwarfism, Down's syndrome and congenital heart disease.
- *Relative generalized*—normal or slightly smaller than normal teeth; are present in jaws that are somewhat larger than normal. It is hereditary. It often exhibits spacing between the teeth.
- *Localized*—it involves only single tooth. It occurs with congenital heart diseases, Down's syndrome and progeria.

Clinical features

- *Location*—most commonly affected teeth are maxillary lateral incisors and 3rd molars. Supernumerary teeth are frequently smaller than normal.
- *Peg shaped lateral*—it is one of the common form of localized microdontia is peg shaped laterals in which the mesial and distal sides converges or taper incisally, forming peg shaped or cone shaped crown (**Fig. 9-1**).
- *Molars*—when molars are involved, they may also undergo a change in shape from five to four cusps in case of mandibular molar and from four to three cusps in upper molars.

Radiographic features

Radiograph will permit evaluation of size of both, erupted and non-erupted teeth.

Diagnosis

- *Clinical diagnosis*—by looking at the size of tooth clinical diagnosis can be easily made.

Fig. 9-1: Peg shape lateral seen in maxillary region showing cone shaped crown.

Management

- *Crown and bridge work*—crown and bridge work is required for esthetic rehabilitation of teeth.

Macrodonia

It is also called as '*megadontia, megalodontia*'. These are the teeth which are larger than normal.

Types

- *True generalized*—all the teeth are larger than normal. It is commonly associated with pituitary gigantism.
- *Relative generalized*—teeth are normal or slightly larger than normal, but present in a smaller jaw.
- *Localized*—one or more large teeth exist in relation to an otherwise normal dentition and body size.

Causes

- *Facial hemihypertrophy*—it is occasionally seen in facial hemi-hypertrophy, in which half of the teeth in unilateral distribution are affected.
- *Gigantism*—in this generalized overgrowth of the body occurs.
- *Genetic*—genetic component also responsible for macrodonia.

Clinical features

- *Teeth size*—teeth are larger than normal (**Fig. 9-2**).
- *Malocclusion*—there is crowding, which may result in malocclusion.
- *Impaction*—as space is less, there is impaction of teeth.

Radiographic features

The increased size will be demonstrated on the radiograph.

Diagnosis

- *Clinical diagnosis*—by looking at the size of tooth clinical diagnosis can be easily made.

Fig. 9-2: Macrodontia of right central incisor showing large size of tooth.

Management

- *Orthodontic treatment*—if necessary orthodontic treatment is done.
- *Extraction*—if impacted, extraction is indicated.

Shape of Teeth

Gemination

It refers to the process whereby, single tooth germ invaginates resulting in incomplete formation of two teeth that may appear as bifid crown on single root. It occurs during the proliferation stage of the growth cycle of tooth. It has got hereditary and familial tendency.

Clinical features

- *Sex*—males and females are equally affected.
- *Sites*—commonly affected teeth are deciduous mandibular incisors and permanent maxillary incisors.
- *Appearance*—it appears clinically as bifid crown on single root.
- *Number of teeth*—it does not increase or decrease the number of teeth present.
- *Crown features*—there are common pulp canals and either single or partially divided pulp chambers. Crown is wider than normal with shallow groove extending from incisal edge to cervical region. Enamel or dentin of crown of geminated teeth may be hypoplastic or hypocalcified.
- *Complication*—areas of hypoplasia and invagination lines or areas of coronal separation represent caries susceptible area, which may lead to pulpal infection. It may also cause malocclusion and periodontal pathosis.

Radiographic features

- *Cleft crown*—cleft in the crown and invagination are usually outlined by the radiopaque enamel which accentuates them.

- *Pulp chamber*—pulp chamber is single, enlarged and may be partially divided.

Diagnosis

- *Clinical diagnosis*—crown appear as bifid on a single root.
- *Radiological diagnosis*—pulp chamber is single and enlarged

Differential Diagnosis

- *Fusion*—tooth structures with two separate root canals and with either one root or two roots are result of fusion, in contrast to the enlarged and possibly partially divided pulp chamber in an enlarged tooth with bifid crown which is a result of gemination. In gemination the full complement of teeth is present while in the case of fusion, tooth is missing.

Management

- *Reshaping of crown*—affected tooth structure should be removed and crown may be restored and reshaped.
- *Periodic disking*—reduction of mesiodistal width with periodic disking.
- *Crown preparation*—final jacket crown preparation.

Twining

It indicates cleavage of tooth germ which results in formation of supernumerary teeth that is mirror image or near image of tooth from which it has developed.

Fusion

It is also called as 'synodontia'. It represents the embryonic union of normally separated tooth germs. It represents junction at the level of dentin between juxtaposed normal tooth germs. Two separate developing tooth germs being initially close together; as they grow and expand; they contact with each other and the germs fuse to varying degrees.

Etiology

- *Genetic*—it is transmitted as autosomal dominant trait with reduced penetration.
- *Physical*—physical force or pressure generated during development causes contact of tooth germs.

Clinical features

- *Sex*—male to female ratio is 1:1.
- *Location*—it is seen more commonly in anterior teeth. It is more common in deciduous dentition than in permanent dentition. It may occur between a normal tooth and a supernumerary tooth such as 'mesiodens' or 'distomolar'.
- *Size of tooth*—tooth is almost twice in size than normal, with or without bifid crown (**Figs 9-3 and 9-4**).

Fig. 9-3: Fusion of central incisor with lateral incisor in the maxillary region.

Fig. 9-4: Fusion of central and lateral incisor showing large tooth.

- *Root canal*—tooth may have separate or fused root canals.
- *Clinical problems*—it may be related to appearance, spacing and periodontal conditions.
- *Significance*—dental caries is common in fused teeth. It may result in reduced number of teeth in the jaws. When deciduous teeth fuse, the corresponding permanent teeth may be absent.

Radiographic features

- True nature and extent of the union will be more evident on radiograph (**Fig. 9-5**).

Diagnosis

- *Clinical diagnosis*—large tooth with missing adjacent tooth will aid in diagnosis.
- *Radiological diagnosis*—fusion can be seen radiography by dentins.

Fig. 9-5: Fusion of tooth with the dentin seen in incisor area (Courtesy Dr Parate).

Differential Diagnosis

- *Gemination*—it is discussed in Differential Diagnosis of gemination.

Management

- *Endodontic treatment*—morphology of teeth should be determined radiographically for endodontic treatment.
- *Reshaping of tooth*—after endodontic treatment, tooth may be reshaped with a restoration that will mimic independent crown.

Concrescence

It is a form of fusion that occurs after the root and other major parts involved in teeth are formed or when the roots of two or more teeth are united by cementum, below the cemento-enamel junction (**Fig. 9-6**). It is also called as 'false gemination'.

Etiology

- *Developmental*—space restriction during development resulting in extends of cementum deposition between closely approximated roots of teeth.
- *Inflammatory*—in cases of inflammatory damage to the roots of teeth are repaired by cementum.
- *Traumatic injury*—this may also lead to concrescence of teeth.
- *Overcrowding*—overcrowding of the teeth with resorption and interdental bone loss.
- *Distal inclination*—distal inclination of crown of molar will results in contact between cementum resulting in concrescence of the tooth.

Types

- *True concrescence*—if the roots are bound during development.
- *Acquired concrescence*—if the condition occurs after development.

Clinical features

- *Sex*—male to female ratio is 1:1.
- *Site and area*—it is common in maxillary 2nd and 3rd molar area. Either primary or secondary teeth are affected. Usually are involved only two teeth, roots are fused by cementum.
- *Significance*—teeth may fail to erupt or incompletely erupt.
- *Malocclusion and impaction*—there may be malocclusion or the teeth may be impacted.

Fig. 9-6: Concrescence is the fusion of tooth by cementum (Courtesy Dr Alka Kale).

Radiographic features

Diagnosis is made by radiographs. It is not always possible to distinguish between concrescence, teeth in close contact and superimposed teeth (**Fig. 9-7**).

Diagnosis

- *Clinical diagnosis*—it is difficult to differentiate between fusion and concrescence.
- *Radiological diagnosis*—radiograph will show union of two teeth with the help of cementum.

Management

Dentist must be careful while doing extraction.

Talon's Cusp

It projects lingually from cingulum area of maxillary and mandibular teeth or it is an anomalous hyperplasia of cingulum on the lingual surface of maxillary and mandibular incisors, resulting in the formation of supernumerary cusp.

Fig. 9-7: Concrescence showing union of the tooth with the help of cementum (Courtesy Dr Mody).

Pathogenesis

- *Focal proliferation*—a focal proliferation of tissue during development.
- *Exuberant development*—exuberant development of the fourth lobe (cingulum) may occur.

Clinical features

- *Sex*—it may be found in both sexes.
- *Location*—it is common in both dentitions. Most commonly seen on maxillary lateral or central incisor.
- *Appearance*—it resembles like an 'eagle's talon'.
- *Signs*—it blends smoothly with the erupted tooth, except that there is deep developmental groove where the cusp blends with sloping lingual tooth surface.
- *Composition*—it is composed of normal enamel, dentin and contains a form of pulp tissue.
- *Shape*—cusp may or may not contain pulp horn and is usually 'T' shaped (**Figs 9-8 and 9-9**).
- *Significance*—patients can face the problems with esthetic. There is also high incidence of caries. Occlusal interference may be there.
- *Syndrome*—it is associated with Rubinstein-Taybi syndrome and Sturge Weber syndrome.

Radiographic features

- Superimposed with incisors, on which it occurs.
- *Appearance*—outline is smooth and a layer of normal appearing enamel is distinguishable (**Figs 9-10A and B**).

Diagnosis

- *Clinical diagnosis*—T shaped elevation on tooth will easily diagnoses talon cusp.

Fig. 9-8: T-shaped talon cusp seen in maxillary lateral incisor (arrow).

Fig. 9-9: Talon cusp seen as T shaped on the tooth (Courtesy Dr Alka Kale).

Differential Diagnosis

- *Supernumerary teeth*—close association can be determined by tube shift technique.

Management

- *Restoration*—prophylactic restoration of the groove should be done to avoid early carious lesion.
- *Endodontic therapy*—removal of cusp followed by endodontic therapy.
- *Periodic grinding*—periodic grinding should be done to maintain vitality of teeth. After grinding, exposed dentin should be coated with desensitizing agents like fluoride varnish.

A

B

Figs 9-10A and B: Talon cusp is seen as radiopacity with smooth outline

Cusp of Carabelli

It is accessory lingual cusp located on the mesiopalatal cusp of maxillary second deciduous molars and 1st, 2nd and 3rd permanent molars (Fig. 9-11).

It may be unilateral or bilateral, with marked deviation in size. In some cases, accessory cusp is seen occasionally on mandibular permanent or deciduous molar. This is called as *protostylid*.

Fig. 9-11: Cusp of Carabelli seen (arrow) in upper first molar.

Dilaceration

It refers to angulations or sharp bends or curve in the roots and crowns of the teeth.

Etiology

- **Trauma**—mechanical trauma to calcified portion of partially formed teeth results in the displacement of calcified portion in dilaceration. The portion formed after accident is in different direction causing the dilaceration.
- **Development defect**—in some cases, it may be form as developmental anomalies.

Clinical features

- **Sex and site**—it is found equally in both sexes. It is most commonly found in maxillary incisors.
- **Appearance**—curve or bending occurs anywhere along the length of tooth, sometimes at cervical portion or midway along the root or even just at the apex of root (Fig. 9-12).

Fig. 9-12: Unusual bend in the root is seen in case of dilaceration (Courtesy Dr Mody).

- **Significance**—sometimes, angles are so acute that a tooth does not erupt. If the defect is in the crown of an erupted tooth, the angular distortion will be recognized.

Radiographic features

- **Location**—it will show angular distortion of unusual relationship between coronal and radicular portion of the tooth, on either side of defect (Fig. 9-13).
- **Root resorption**—there may be inappropriate resorption of deciduous tooth which will delay the eruption of permanent teeth.
- **Appearance**—if the malformed teeth bend over the fold, the defect will be obscured. If the root bends mesially or distally condition will clearly appear on radiograph.
- **Buccal and lingual dilaceration**—when it is tilted buccally or lingually, dilacerated portion will appear at apical end as a rounded opaque area with dark shadow in central region by apical foramen. Periodontal space about this is evidenced as a radiolucent halo.

Fig. 9-13: Bending of root occur in the middle portion of the teeth.

Diagnosis

- **Clinical diagnosis**—not possible.
- **Radiological diagnosis**—radiograph will show curved root.

Differential Diagnosis

- **Fused root**—in this case, you will be able to find two different root canals.
- **Condensing osteitis**—the tooth is non-vital in case of condensing osteitis.

Management

- **Difficult extraction**—difficulty at the time of extraction.
- **Restoration**—dilacerated crown has to be restored improve esthetics and function and to preclude dental caries and periodontal disease.

Dens in Dente

It is also called as 'dens invaginatus' or 'dilated composite odontome' or 'gestant odontome'. Infolding of the outer surface

of the tooth into its interior surface occurs. It is a developmental variation which is thought to arise as a result of an invagination in the surface of crown before calcification.

Etiopathogenesis

- *Focal growth retardation*—according to Kronfeld, there is relative retardation in growth of a portion of the enamel organ. Due to this, part of the tooth remains stationary and the remaining grows around it causing invagination.
- *Active proliferation*—according to Swanson and McCarthy, it occurs due to proliferation of enamel organ at the inner epithelium apically into dental papilla during the stage of differentiation of developing tooth germ. It grows into dental papilla, as a sort of adenoma.
- *Continuous differentiation*—Rabinowitch said that, it may be formed by continued differentiation of some cells of the inner enamel epithelium.
- *Increased pressure*—study shows that there is presence of extravascular fluid in the soft tissue that fills the potential invagination cavity of the tooth, before it erupts, suggesting that there is increased venous pressure within the invagination. It could be due to pressure on the blood vessels as they pass through the entrance channel of the invagination cavity where enamel is forming concentrically and centripetally, thus tending to progressively narrow the entrance. Expansion of the invagination could then result from the increased venous pressure and transudation.
- *Local causes*—it can occur due to the infection of the deciduous predecessor or trauma. Pressure on the growing teeth can also cause invagination.

Classification

1st classification

- *Coronal dens invaginatus*—it is anomalous infolding of enamel organ into dental papilla. It results in the fold of hard tissue within the tooth, characterized by enamel lining the fold and covering the dentin peripheral to it.
- *Radicular dens invaginatus*—it is a result of invagination of Hertwig's epithelial root sheath resulting in accentuation of normal longitudinal root grooves. It is lined by cementum. Root sheath may bud off sac like invagination that results in a circumscribed cementum defect in root.

2nd classification depending upon site of invagination given by Ohler

- *Type I*—invagination limited to the crown.
- *Type II*—invagination extending to cemento-enamel junction.
- *Type III*—invagination extends beyond the cemento-enamel junctions. It is commonly seen in 2nd premolar either periapical tissue or in the periodontal ligament.

3rd classification given by Aguilo et al

- *Type I*—bifid crown with single root (the crown is larger than normal with notch on the incisal edge and bifid pulp chamber)
- *Type II*—large crown with large root (the crown is larger than normal and there is no groove present. The root is wider than normal with single large pulp canal.
- *Type III*—two fused crown with single root (there are two crown with vertical groove. Root is conical and pulp chamber are separate).
- *Type IV*—two fused crown with two fused root (two crown with vertical groove. The cervical portion are joined along the pulp chamber).

Clinical features

Coronal dens invaginatus

- *Age and sex*—it is seen in children and adolescents. It is more common in females.
- *Site*—commonly affected tooth is permanent maxillary lateral incisor and maxillary central incisor. The lower incisor or cuspid is the next common site. This condition is frequently bilateral.
- *Appearance*—in some cases, there appears to be a grossly magnified cingulum rising to the level of the incisive edge of the tooth, but lacking the normal contour of a cingulum. The labial face of the tooth is often bulbous. Some teeth with these abnormalities are so misshapen as to defy verbal description (**Fig. 9-14**).
- *Crown features*—the crown may or may not be enlarged. The shape of crown may be conical or it may be of irregular shape.
- *Mild form*—there is a deep pit in cingulum.
- *Moderate*—in this type, pocket of enamel is formed within tooth, with dentin at periphery. Opening to the surface

Fig. 9-14: Dens invaginatus showing infolding of outer surface of tooth.

is constricted or remains open. Food debris may become packed in this area with resultant caries and infection of pulp.

- *Severe form*—it may exhibit an invagination extending nearly to the apex of the root.

Radicular dens invaginatus

- *Site*—it is more common in 1st mandibular premolar, upper lateral incisor and second molar. Abnormality is usually unilateral. It occurs most frequently at the site of anatomical defect. It is rare phenomenon.
- *Crown features*—crown is small, short and conical with small orifice at the extreme summit of the convexity. Lingual marginal ridge is prominent.
- *Root features*—cavity is separated from the pulp chamber by a thin wall and opens in oral environment through very narrow constriction.

Radiographic features

Coronal dens invaginatus

- *Radiodensity*—infolding is recognized by its greater radiodensity (**Fig. 9-15**).
- *Size*—it may vary in size from very small and superficial, to large and deep.
- *Pulp chamber*—in addition to small but otherwise normal pulp chamber, there is sometimes an additional cavity of variable shape and size which may be separated from real pulp chamber or may unite with it.

Fig. 9-15: Dens in dente showing infolding of the enamel in the crown of tooth presented as greater radiodensity.

Radicular dens invaginatus

- *Radiodensity*—radicular invagination will appear as a poorly defined, slightly radiolucent structure running longitudinally within the root.

- *Appearance*—the root is composed of a saucer shaped expansion, the concavity of which represents the dilated feature of the tooth.
- *Inverted open umbrella*—the tooth resembles 'inverted open umbrella', the handle of which is short, being represented by the conical, nipple-shaped crown (**Fig. 9-16**).
- *Size*—the diameter of expanded portion of the root, at the extreme apex is as much as 2 cm.
- *Apical foramina*—apical foramina of the root is wide.
- *Apical area*—there is always area of radiolucency present in the bone at the end of the radicular portion as a result of rarefying osteitis, which has followed the passage of organism from the mouth upto the canal in the tooth.

Fig. 9-16: Dens invaginatus showing inverted umbrella appearances (Courtesy Dr Parate).

Diagnosis

- *Clinical diagnosis*—infolding of tooth is seen clinically
- *Radiological diagnosis*—inverted umbrella appearance seen radiographically.

Management

To prevent caries, pulp infection and premature loss of tooth, dense in dente must be treated prophylactically.

Dens Evaginatus

It is also called as 'Leong's premolar', 'evaginated odontome' or 'occlusal enamel pearl'. Dens evaginatus is a developmental condition that appears clinically as an accessory cusp or globules of enamel on occlusal surface, between buccal and lingual cusps of premolar.

Pathogenesis

It is caused by proliferation and evagination of an area of inner enamel epithelium and subsequent odontogenic

mesenchyme into dental organ, during early tooth development.

Clinical features

- **Site**—it occurs on premolar and molar teeth and usually occurs unilaterally or bilaterally.
- **Race**—it develops in persons of Mongoloid ancestry.
- **Composition**—it consists of all three dental tissues, i.e. enamel, dentine and cementum.
- **Appearance**—it appears as a tubercle of enamel on occlusal surface of the affected tooth. Polyp-like protuberance in central groove, on lingual ridge of buccal cusp is seen.
- **Significance**—there may be incomplete eruption. Displacement of teeth with pulp exposure and subsequent infection may present, following occlusal wear or fracture.

Radiographic features

- **Dentin and enamel**—dentin core is covered with opaque enamel.
- **Pulp**—fine pulp horns may be apparent. Pulpal extension is seen in the cusp of the tooth.
- **Tuberculated appearance**—occlusal surface have tuberculated appearance (**Fig. 9-17**).

Fig. 9-17: Tuberculated appearance seen on the occlusal surface of first molar.

Diagnosis

- **Clinical diagnosis**—tubercle on occlusal surface of enamel is the key to diagnosis.
- **Radiological diagnosis**—tuberculated appearance of occlusal surface.

Management

- **Grinding of tubercle**—if tubercle is a cause of occlusal interference, it should be removed and should be followed by indirect pulp capping with calcium hydroxide.
- **Composite reinforcement**—it should be done to protect a cusp from the fracture.

Shovel Shaped Incisors

It is morphologically an anomaly of the crowns of incisor teeth. It is more common in the maxillary teeth.

The shovel shape is manifested by the prominence of the mesial and distal marginal ridges which enclose a central fossa on the lingual surface of incisor teeth. It has frequently a short root (**Fig. 9-18**).

Fig. 9-18: Shovel shaped incisor diagrammatic representation.

Taurodontism

It is described in 1913 by *Sir Arthur Keith*. In this, body of tooth is enlarged at the expense of root. It is characterized by clinical and anatomical crown of normal shape and size, an elongated body and short roots with longitudinally enlarged pulp chambers. Taurodont teeth resembles that of cud-chewing animal (tauro- bull and dont-tooth).

Etiology

- **Hereditary**—it is caused by genetically determined trait.
- **Developmental**—it occurs due to failure of Hertwig's epithelial root sheath to invaginate at proper horizontal level.
- **Mutation**—resulting from odontoblastic deficiency during dentinogenesis of the root.

Classification

- **Hypotaurodont**—it is mild form of Taurodont and it represents slightly apical displacement of pulpal floor.
- **Mesotaurodont**—it is moderate form and pulpal floor displacement is about midline of the root of teeth (**Fig. 9-19**).
- **Hypertaurodont**—it is severe form and apical displacement of pulpal floor is present at the apex.

Clinical features

- **Sex and age**—it is common in early aged men. It has got no sex predilection.
- **Site**—it may affect either deciduous or permanent dentition and teeth involved are invariably molars. It may be unilateral or bilateral, or may exhibit any combination of quadrant involvement.
- **Shape**—involved teeth tend to be of rectangular shape rather than the normal tapering towards root.

- *Associated conditions*—it may associate with certain dermatological condition like epidermolysis bullosa, otodental dysplasia and dyskeratosis congenita.
- *Associated syndromes*—Klinefelter syndrome, Rapp Hodgkin, Down and Trichodontoosseous syndrome.

Fig. 9-19: Moderate form of taurodontism seen in molar teeth (Courtesy Dr Tapasya Karamore).

Radiographic features

- *Pulp and pulp chamber*—pulp chamber is extremely large with much greater apicoocclusal height than normal. Extensions of rectangular pulp chamber occur into elongated body of the tooth. Pulp lacks the usual constriction at the cervix of tooth.
- *Roots*—the root and root canals are exceedingly short. Increased dimension between cemento enamel junction and furcation.

Diagnosis

- *Clinical diagnosis*—rectangular shaped crown.
- *Radiological diagnosis*—extremely large pulp chamber.

Differential diagnosis

- *Developing mandibular molar*—it has got wide apical foramina; the incomplete root and dental papilla will rule out taurodontism.

Management

No specific treatment is necessary as it does not cause any clinical problems.

Supernumerary Roots

Teeth that are normally single rooted exhibit two roots.

Clinical features

- *Sites*—both, maxillary and mandibular molars particularly 3rd molars, exhibit supernumerary roots.
- *Appearance*—they develop as slender outgrowths at the center of furcation area of molar teeth.

Radiographic features

- If the bifurcation produces two distinct apices and these are arranged as one mesial to the other, then it will be seen on the radiographs (**Fig. 9-20**).

- If the two apices are on the labial and lingual side, they may get superimposed on each other appearing as a bulbous root, which may mimic hypercementosis.

Fig. 9-20: Supernumerary root is seen in mandibular first molar.

Differential Diagnosis

- *Hypercementosis*—in a case when root appears bulbous due to superimposition of root on the labial and lingual surfaces, hypercementosis should be ruled out. In a tooth with supernumerary roots, the pulp canal may appear to end a short distance from the blunt square end apex. Arising from blunt end to the canal, are two fine channels which extend one into each root, these channels suggest the presence of two apices, thus excluding hypercementosis.

Management

- Assume significance only during exodontia as these roots may be broken off during extraction.

Paramolar Tubercle or Bolk Cusp

It appears as a nodular elevation. It is seen most frequently on the buccal surface of mesiobuccal cusp in permanent and primary molars.

Enamel Pearls or Droplet, Nodules

It is also called as 'enameloma, ectopic enamel'. It is presence of enamel at unusual location. Pearls or droplets are described as small buttons or nodules of enamel, usually about 1 mm or 2 mm in diameter, that form on the root, or at bifurcation or trifurcation of multirooted teeth.

Pathogenesis

- *Activity of Hertwig's epithelium*—It arises from local activity of remnants of Hertwig's epithelium before it reduces to rests of Malassez.

Clinical features

- *Site*—it is common in trifurcation of maxillary molars, followed by bifurcation of mandibular molars. Those

found on maxillary molars are usually on mesial or distal aspect. In contrast, to those on mandibular molars, which are most often on buccal or lingual aspect.

- **Significance**—rarely, small pulpal extensions may reach into center of nodule and thereby, constitute additional hazard. Rarely, tiny nodule may be sufficiently close to gingival margin to become involved in the periodontal problems.
- **Cervical enamel extension**—they are located on the buccal surface of the root over bifurcation area. In this, localized loss of periodontal attachment with furcation involvement occurs. Cervical enamel extension may also lead to development of buccal bifurcation cysts.

Radiographic features

- **Appearance**—it appears as smooth, round and well defined radiopacity present along the root surface. Radiodensity is same as that of the enamel (**Fig. 9-21**).
- **Pulp**—it may have small core of dentin and rarely pulp horn from the chamber of host teeth.

Fig. 9-21: Enamel pearl seen as rounded opacity on the radiograph.

Diagnosis

- **Clinical diagnosis**—not possible.
- **Radiological diagnosis**—rounded opacity in the furcation area.

Differential Diagnosis

- **Calculus**—clinically detectable.
- **Pulp stone**—can be diagnosed by changing angulation.

Management

- **Maintain oral hygiene**—oral hygiene should be maintained. If it is causing periodontal problems, mass can be removed.

Globodontia or Otodental Syndrome

It is also called as 'otodental dysplasia', 'familial otodontodysplasia'. The term globodontia refers to the enlarged bulbous fused malformed posterior teeth with almost no discernable cusps or grooves. The otodental syndrome also named otodental dysplasia is characterized by a striking dental phenotype known as globodontia, associated with sensorineural high frequency hearing loss and eye coloboma. The condition appears to be inherited in an autosomal dominant mode, although sporadic cases have been reported.

Clinical features

- **Location**—globodontia occurs in both primary and permanent dentition, affecting canine and molar teeth.
- **Age**—age of onset is in fourth decade but it can be seen in early childhood.
- **Appearance of teeth**—Enlarged bulbous malformed posterior teeth with almost no discernable cusps or grooves. Teeth have a round globular or clover leaf appearance (**Fig. 9-22**). The relation between cusps and the major groove is eliminated hence, used the term *globodontia*.
- **Gingiva**—gingiva is inflamed and enlarged. Gingival hyperplasia was a common clinical finding around erupting teeth.
- **Eruption**—there was a significant delay in eruption of the primary and permanent dentition. The primary teeth might exfoliate lately.
- **Decay**—teeth might prone to decay.
- **Malocclusion**—posterior bilateral cross-bite, anterior open bite can also be present.
- **Hearing loss**—there is sensorineural high frequency hearing loss. Hearing loss is progressive and bilateral.
- **Eye defect**—abnormalities ranged from transillumination defects in the inferior iris, due to iris pigment epithelium

Fig. 9-22: Globodontia showing globular pattern with fusion of cusp.

defects, to severe chorioretinal coloboma. Other ocular signs are microcornea, microphthalmos, lens opacity and lens coloboma.

- *Nevi*—several small deeply pigmented lesions are present on faces and scalps.
- *Ears*—ears were protuberant. In some cases ear abscesses are also noted.
- *Stature*—constitutional short stature is also seen.

Radiological features

- Tooth shape is globular with increased radiopacity
- Roots were short and exhibits taurodontism (**Fig. 9-23**)

Fig. 9-23: Short roots seen in case of globodontia.

Diagnosis

- *Clinical diagnosis*—globular portion of tooth can be diagnosed clinically.

Management

- Regular follow up, scheduled tooth extraction and eventually orthodontic treatment should be done.

Mulberry Molar

It is a characteristic syphilitic lesion of posterior teeth in which hyperplastic enamel develops with spherical aggregates or globules on the surface of dentin.

Moon's Molar

It is syphilitic lesion of posterior teeth. 1st molar is commonly involved. Cusp of teeth show exaggerated rounded or nodular shapes.

Appearances—it is often grossly distorted, usually narrower mesiodistally with loss of angulation of occlusal edge, which may give cusp a squarish appearance.

Hutchinson's Incisor

Commonly affected teeth are the anterior teeth. Center of the incisal edge shows typical notching. An affected tooth

is screwdriver shaped, with tapering marginal ridges converging towards the incisor edge. Teeth may show barrel shaped outline.

Hypercementosis

It is also called as '*cementum hyperplasia*' or '*exostosis of root*'. It is characterized by deposition of excessive amount of cementum on the root surface. New tissue formation is in direct contact with the cementum of roots of teeth.

Types

- *Localized*—hypercementosis of single tooth. It is usually a reactive, inflammation dependent phenomenon seen on single tooth and usually in relation to periapical osteitis or due to loss of occluding antagonistic tooth.
- *Generalized*—generalized hypercementosis affecting many (all) teeth, but which is seldom recognized as such, occurs with increasing age, i.e. as an age dependent factor. It is also seen as a sign accompanying specific diseases, as for instance, Paget's disease of bone.

Etiology

- *Loss of antagonist*—there is accelerated elongation of tooth occurs due to loss of antagonist. It occurs due to inherent tendency of the periodontium to maintain normal width of the periodontal ligament.
- *Inflammation of the root*—it does not occur at the apex of the root directly adjacent to the area of inflammation, as cementoblasts and their direct precursors in this area are lost. Instead, it occurs at some distance above the apex as the inflammatory reaction acts as stimulation for the cementoblasts.
- *Trauma repair*—occlusal trauma results in mild root resorption and it is then repaired by cementum formation. Root fracture is also repaired on occasion by deposition of cementum between the root fragments as well as in their periphery.
- *Osteitis deformans or Paget's disease of bone*—it is a generalized skeletal disease characterized by excessive amount of cementum formation on roots of teeth and by apparent disappearance of lamina dura of teeth.
- *Others*—other disease which can cause hypercementosis are hyperpituitarism, calcinosis, thyroid goiter, vitamin A deficiency, cleidocranial dysostosis and rheumatic fever.

Clinical features

- *Age*—it is predominately seen in adults.
- *Site*—premolar teeth are often bilaterally affected and symmetrical in distribution. The permanent teeth are affected more commonly than deciduous teeth. In multirooted teeth, one or more roots are involved.

- *Symptoms*—there is no increase or decrease in tooth sensitivity, unless periapical infection is present.
- *Signs*—teeth are vital and not sensitive to percussion. There may be difficulty in extraction of teeth.
- *Fusion of teeth*—in some cases, hypercementosis is so extensive that it causes fusion of two or more adjacent teeth.
- *Roots*—roots appear larger in diameter than normal and present rounded apices.
- *Spike formation of cementum*—it is characterized by occurrence of small spikes or outgrowth of cementum on root surface. It occurs in cases of excessive occlusal trauma probably due to deposition of irregular cementum in focal group of periodontal ligament fibers (Fig. 9-24).

Fig. 9-24: Hypercementosis of third molar seen as excessive cementum deposition around the third molar (Courtesy Dr Ashok L).

Radiographic features

- *Appearance*—there is thickening and apparent blunting of root with rounding of apex. If cementum is distributed eccentrically there is a localized protuberance
- *Apex*—apex appears bulbous in some instances, after symmetrical distribution of cementum.
- *Lamina dura*—lamina dura will follow the outline of teeth in normal periodontal ligament space.
- *Bone resorption*—there may be mildly irregular accumulation of cementum that is accommodated by related area of bone resorption.

Diagnosis

- *Clinical diagnosis*—not significant.
- *Radiological diagnosis*—bulbous appearance of root of tooth due to cementum deposition.

Differential Diagnosis

- *Multirooted teeth and dilacerated root*—successive radiographs from different angle should be taken.
- *Fused root*—recognized by expanded region of root that does not have lower radiodensity of hyperplastic cementum.

Management

- Treatment of the primary cause should be done.

Number of Teeth

Anodontia, Hypodontia and Oligodontia

Several terms are used to discuss number of missing teeth. It is congenital absence of teeth.

Classification

- *True*—it is congenitally absence of teeth
 - *Anodontia*—it is complete lack of tooth development.
 - *Hypodontia*—it is lack of development of one or more teeth (Fig. 9-25).
 - *Oligodontia*—it is lack of development of six or more teeth (Fig. 9-26).
- *False*—it occurs due to extraction of teeth.
- *Pseudo*—it occurs due to multiple unerupted teeth in the jaw.

Fig. 9-25: Hypodontia showing missing teeth in upper anterior region.

Fig. 9-26: Oligodontia showing missing teeth which is more than six in number (Courtesy Dr Parate).

Etiology

- *Genetic*—many hereditary syndromes have been associated with less number of teeth. More commonly they are hereditary ectodermal dysplasia, cleidocranial

dysplasia, craniofacial dysostosis, book syndrome, Coffin-Lowry syndrome, otodental dysplasia etc.

- *Evolutionary trends*—nowadays there is evolutionary trend towards few teeth.
- *X-ray radiation*—this may cause harm to the developing tooth bud resulting in missing teeth.

Clinical features

- *Sex and race*—it is higher in women and most probably in Mongoloid, than whites.
- *Location*—absence may be unilateral or bilateral. Commonly missing are 3rd molar, maxillary lateral incisor (**Fig. 9-27**), maxillary or mandibular 2nd premolar.
- *Associated feature*—associated features include microdontia, reduced alveolar development, increase freeway space and retained primary teeth.

Fig. 9-27: Hypodontia seen in lady patient showing many missing teeth.

Management

- *Orthodontic treatment*—it should be carried out as many patients may develop malocclusion.
- *Prosthesis*—traditional fixed prosthesis and resin bonded bridges should be given.

Supernumerary Teeth

It is also called as '*hyperdontia*'. It is defined as any tooth or tooth substance in the excess of the usual configuration of twenty deciduous or thirty two permanent teeth.

Pathogenesis and etiology

The various factors which are responsible for formation of supernumerary teeth as follows:

- *Phylogenetic reversion theory*—this theory is nowadays discarded.
- *Dichotomy theory*—this theory states that tooth bud is split to form two different tooth,
- *Hyperactivity of dental lamina*—a supernumerary tooth develops from 3rd tooth bud arising from dental lamina near the permanent tooth bud.

- *Hereditary*—it is inherited as an autosomal dominant trait, when associated with syndromes. It is inherited as an autosomal recessive trait when associated with only supernumerary teeth. Supernumerary teeth are most commonly found in relative of affected children than in general population.

Types of supernumerary teeth

It is based on form, and location of teeth.

According to form

- *Supplemental supernumerary teeth*—these teeth duplicate the typical anatomy of posterior and anterior teeth.
- *Rudimentary supernumerary teeth*—these are dysmorphic and can assume *conical* (**Fig. 9-28**) or *tuberculated* forms.
- *Odontome like*—in some cases odontome may be form in place of supernumerary teeth.

Fig. 9-28: Conical type of supernumerary teeth present in anterior maxillary region.

According to location

- *Mesiodens*—it is located at or near the midline in the incisal region of maxilla between central incisors (**Fig. 9-29**). It may occur singly or paired, erupted or impacted or even inverted. It is a small tooth with cone shaped crown and short root. It may cause retarded eruption, displacement or resorption of adjacent root. It frequently causes improper alignment.
- *Distomolar*—it is found in molar region frequently located distal to 3rd molar (**Fig. 9-30**). Generally, these teeth are smaller than normal 2nd and 3rd molar (**Fig. 9-31**), crown morphology is highly abnormal.
- *Paramolar*—it is supernumerary molar, usually small and rudimentary and is situated buccally or lingually to one of the maxillary molars or interproximally between 1st, 2nd and 3rd maxillary molars.
- *Peridens*—supernumerary teeth that erupt ectopically, either buccally or lingually to the normal arch are referred as peridens (**Fig. 9-32**).

Fig. 9-29: Inverted pair of mesiodense present.

Fig. 9-30: Distomolar seen distal to third molar.

Fig. 9-31: Distomolar seen in maxillary third molar region.

Fig. 9-32: Peridens seen erupted lingually in mandibular premolar region (Courtesy Dr Bhaskar).

Clinical features

- **Prevalence**—the prevalence of supernumerary teeth is about 0.1 to 3.6% of the population.
- **Sex**—males are affected more than females. Male to female ratio is 2:1.
- **Dentition**—it may occur in both dentitions, but frequently found in permanent dentition and more often in mandible.
- **Site**—it is more commonly seen in anterior maxilla (Fig. 9-33A) followed by mandibular premolar region (Fig. 9-33B).

Fig. 9-33A: Supernumerary teeth seen more commonly in maxilla.

- **Effect on dentitions**—supernumerary teeth frequently prevent permanent teeth from erupting. In some cases eruption taken place in abnormal direction. There may be crowding, root resorption of adjacent tooth and malformation of teeth. In some cases supernumerary teeth may be associated with cyst formation.
- **Syndromes**—it is associated with cleidocranial dysplasia, orofacial digital syndrome, Down, Laband, Sturge Weber and Gardner's syndrome.

Fig. 9-33B: Supernumerary teeth seen in mandibular premolar region.

Radiographic features

- *When it is needed*—if abnormal clinical signs are present you can go for OPG examination, IOPA, occlusal radiographic examination.
- *Significance*—radiograph will aid in determining the location and number of unerupted teeth. It can also be used to see if there is any cyst formation.
- *Appearance*—their radiographic picture is characteristic of teeth.

Management

- *Surgical extraction*—it depends on potential effect on normal dentition, their position, number and complications that may result from surgical removal. If required, they should be extracted.

Pre-decious Dentition

It is also called as 'congenital teeth', 'fetal deciduous teeth', 'dentition proceox' and 'natal and neonatal teeth'. There is premature eruption of teeth or teeth like structures that are present at birth.

Natal teeth are the teeth which are present at the time of birth and *neonatal teeth* are the teeth which are present within 30 days after the birth.

Etiology

- *Hereditary*—superficial position of tooth germ.
- *Hormonal influence*—eruption accelerated by febrile incident or hormonal stimulation.

Classification

- *Mature*—they are fully developed in shape and comparable in morphology to the primary teeth. Prognosis is relatively good.
- *Immature*—their structure and development is incomplete. Poor prognosis of teeth.

Clinical features

- *Appearance*—teeth may be conical or may be normal in size and shape and opaque yellow-brownish in color.
- *Signs*—they are hypermobile because of their limited root development. Within relatively short time, premature erupted tooth will become stabilized and other teeth of the arch are erupted. Teeth appear to be attached to a small mass of soft tissue.
- *Significance*—some teeth are so much mobile that there is danger of displacement and possible aspiration and in this case, removal is indicated.
- *Riga fede ulcer*—there is ulceration of the ventral surface of the tongue caused by the sharp incisal edges (Figs 9-34 and 9-35). It leads to interference with proper suckling and feeding and thus the neonate is at risk of nutritional deficiency.
- *Associated syndromes*—it may associate with syndromes like Ellis-van Creveld syndrome and cleft palate.

Fig. 9-34: Ulcer seen on the tongue due to natal teeth.

Fig. 9-35: Neonatal teeth causing ulceration on the ventral surface of the tongue.

Radiographic feature

- Radiographs fail to show any root substance and teeth are very small to represent the normal teeth.

Management

- *Extraction*—extraction of the teeth should be carried out if it is causing inconvenience during suckling, interference with breastfeeding and causing traumatic injury. Extraction should be done after 10 days of life.
- *Rounding of sharp angle*—the other option that may be used is rounding of the sharp angle of incisal edges of teeth.
- *Retaining the tooth*—if not necessary, tooth should not be removed.

Post-permanent Dentition

Persons who have all the permanent teeth extracted and yet have subsequently erupted teeth, particularly after insertion of complete denture come in this category. They possibly develop from bud of dental lamina beyond the permanent tooth germs.

Structure of Teeth**Amelogenesis Imperfecta**

It is also called as 'hereditary enamel dysplasia', 'hereditary brown enamel' and 'hereditary brown opalescent teeth'.

It represents group of hereditary defects of enamel associated with any other generalized defect. It is an ectodermal disease and mesodermal component is normal.

Classification

Classification depends upon the stage of at which the disease occurs. According to it, there are mainly three types of amelogenesis imperfecta

- *Hypoplastic type*—there is defective formation of enamel matrix.
 - *Autosomal dominant*
 - Generalized pitted
 - Localized pitted
 - Diffuse smooth
 - Diffuse rough
 - *Autosomal recessive*
 - Localized pitted
 - Enamel agenesis
 - *X-linked dominant*
- *Hypocalcification type*—there is defective mineralization of formed matrix.
 - *Autosomal dominant*
 - *Autosomal recessive*
- *Hypomaturational type*—in this, enamel crystal lattice remains immature.
 - *Autosomal dominant*
 - *Autosomal recessive*
 - *Snow-capped teeth*.

Clinical features**Hypoplastic type**

It includes localized portions of enamel that do not reach normal thickness during development.

Autosomal dominant

- *Generalized pitted*—it appears as thin enamel on teeth that do not contact with each other mesiodistally. Pinpoint to pinhead pits are randomly distributed over the surface. Enamel on newly erupted teeth is hard with normal yellow-white color. Staining of teeth occurs after exposure to oral environment, giving teeth a black appearance.
- *Localized pitted*—horizontal rows of depressions or one large hypoplastic area with hypocalcification adjacent to and below the hypoplastic area is found. Defects are most prominent on buccal surfaces of the teeth, involving middle 3rd of enamel. Incisal or occlusal surfaces of the teeth are usually not involved.
- *Diffuse smooth*—in this enamel is thin, hard and glossy with smooth surface (**Fig. 9-36**). Enamel is 1/4th to 1/8th of its normal thickness. On newly erupted teeth, they have yellow color, but may vary from opaque white to translucent brown. Some of the enamel may be missing on newly erupted teeth, especially on the incisal and occlusal surface and may be chalky in inter-proximal areas. Delay in eruption occurs with resorption of teeth in the alveolus.

Fig. 9-36: Smooth type of amelogenesis imperfecta showing glossy smooth surface.

- *Diffuse rough*—enamel is hard with rough granular surface that may be chipped from underlying dentin, rather than abrade away as seen with smooth type. Enamel is 1/4th to 1/8th in thickness. Teeth are white to yellow-white when newly erupted. Teeth do not meet at contact points but retain normal tooth outline than the smooth type of imperfecta. It may have thicker enamel at cervical areas. Anterior open bite present.

Autosomal recessive type

- *Localized pitted*—this is severe form than autosomal dominant type. In this, all the teeth are involved in both dentition.
- *Enamel agenesis*—teeth which are erupted have distinct yellow color like normal dentition. Surface is rough and granular, resembling ground glass. There is complete lack of enamel formation. Teeth are widely spaced and do not meet each other at contact point. Patient may have anterior open bite. Numerous teeth are missing in the dentition.

X-linked dominant

- *In males*—there is diffuse, thin smooth shiny enamel in both dentitions. Open contact point. The color varies from brown to yellow-brown.
- *In females*—females will exhibit furrows of thin hypoplastic enamel alternating between bands of normal thickness.

Hypocalcified

In this, enamel matrix is formed normally but without significant mineralization. The enamel is so soft that it can be removed by a prophylaxis instrument.

Autosomal dominant and autosomal recessive

- *Thickness of enamel*—enamel is of normal thickness, although occasional areas of hypoplasia are seen on middle 3rd of labial surface.
- *Consistency of enamel*—the enamel is so soft that it may be lost soon after eruption, leaving crown composed of only dentin (**Fig. 9-37**). Enamel has cheesy consistency and can be scraped from dentin with an instrument or penetrated easily by dental explorer.
- *Color of enamel*—newly erupted teeth are covered with dull lusterless opaque, white, honey colored or yellowish orange or brown enamel.
- *Significance*—exposed dentin may be hypersensitive. Anterior open bite may be present. Patients with this condition are prone to form calculus rapidly.

Fig. 9-37: Hypocalcified type showing loss of enamel in maxillary as well as mandibular teeth (Courtesy Dr Parate).

Hypomaturation type

In this there is defect in the maturation of enamel crystal structure. The enamel can be pierced by an explorer point under firm pressure and can be lost by chipping away from the underlying, normal appearing dentin.

Autosomal dominant

- *Sex*—it is more commonly found in males.
- *Dentition*—both primary and permanent dentitions are affected
- *Color of teeth*—permanent teeth are mottled yellow white in color, but may be darkened with absorption of stains (**Fig. 9-38**). Primary teeth of affected males have ground glass opaque white appearance. Patient occasionally shows slight yellow cast to enamel surface.
- *Intact contact point*—teeth meet at contact points and have normal contour.
- *Thickness of enamel*—enamel approaches normal thickness, but it may be thinner. Point of explorer can be forced into enamel.

Fig. 9-38: Amelogenesis imperfecta of Hypomaturation type showing brown discoloration of teeth.

Autosomal recessive or pigmented type

- *Dentition*—both primary and permanent dentitions are affected.
- *Color of teeth*—enamel has milky to shiny, agar brown color on newly erupted teeth. It may become more deeply stained on contact with exogenous agents.
- *Thickness of enamel*—teeth are of normal thickness and tend to chip away, especially around restoration.
- *Pigmentation*—patient tends to form large amount of calculus which may contain pigment forming agents.
- *Resorption of teeth*—teeth may be seen undergoing resorption within alveolus.

Snow capped teeth

- *Site*—maxillary teeth are affected more commonly than mandibular one.

- *Dentition*—both primary and secondary dentitions are affected.
- *Color of teeth*—in this condition varying amount of enamel on incisal or occlusal aspect of crown is present and has opaque white appearances. Opacity may be solid or flecked and may involve enamel surface. Junctional line of opaque white and translucent enamel is sharp.
- *Dipped into white paints appearance*—pattern of defect on teeth anterior to the posterior teeth resemble that which would be obtained when ‘dipped into white paints’.

Radiographic features

- *Loss of contour*—squarish type of crown being devoid of the normal mesial and distal contours (**Fig. 9-39**).
- *Enamel*—the normal enamel cap is missing and in its place, there is thin and opaque layer of enamel. There may be low and absent cusps, with series of serrations of varying sharpness. There is lack of contrast between enamel and dentin, the whole of the crown presenting a uniform density.
- *Pulp chamber*—if abrasion is advanced then there is obliteration of pulp chamber.
- *Hypoplastic type*—the pitted enamel will appear as areas of mottled density.
- *Hypocalcified type*—in case of hypocalcified type, teeth have moth eaten appearance on radiograph.
- *Hypomaturational type*—in hypomaturational type, enamel is less radiolucent than normal.

Fig. 9-39: Loss of contour seen between the teeth in amelogenesis imperfecta.

Diagnosis

- *Clinical diagnosis*—cheesy consistency of enamel with loss of enamel aid in diagnosis of amelogenesis imperfecta.
- *Radiological diagnosis*—missing enamel cap with low or absent cusp.

Differential Diagnosis

- *Dentinogenesis imperfecta*—Shape and size of crown and root with relatively normal density, obliteration of pulp chamber and root canals in the absence of any marked abrasion should identify dentinogenesis imperfecta.

Management

- *Cosmetic improvement*—it should be done with the help of placement of crown or facial veneer on the teeth.

- *Desensitizing agent*—this should be given to manage the sensitivity which occur to patient due to exposure of dentin.
- *Overdenture*—this should be given to that patient who doesn't have sufficient crown length for the restoration.

Dentinogenesis Imperfecta

There are various names for dentinogenesis imperfecta like ‘hereditary opalescent dentin’ and ‘Capadepon's teeth’. It segregates as an autosomal dominant trait with variable expressivity.

Classification

- *Shield type I*—dentinogenesis imperfecta always occurs with osteogenesis imperfecta. According to Witkop it is called as dentinogenesis imperfecta
- *Shield type II*—It does not occur in association with osteogenesis imperfecta. According to Witkop it is called as ‘hereditary opalescent dentin’.
- *Shield type III*—It has got shell teeth appearance and multiple pulp exposure. According to Witkop it is also called as ‘Brandywine type’.

Clinical features

Shield type I

- *General features*—features of this condition are multiple bone fractures, hyperextensible joints, blue sclera and progressive deafness.
- *Dentition*—deciduous teeth are more severely affected than permanent teeth.
- *Color of teeth*—color of teeth may vary from blue to brownish violet to yellowish brown. Amber translucency of both primary and permanent dentition may be seen (**Fig. 9-40**).
- *Rapid attrition*—enamel may be lost and dentin undergoes rapid attrition (**Fig. 9-41**).

Fig. 9-40: Bluish type of discoloration seen in case of dentinogenesis imperfecta.

Fig. 9-41: Dentinogenesis imperfecta showing rapid loss of enamel (Courtesy Dr Chole).

- **Teeth**—usual scalloping of dentinoenamel junction is absent. The teeth are shorter than normal often markedly, in respect to the roots and crowns. In some cases, there is total crown lost (**Fig. 9-42**).

Fig. 9-42: Total crown lost in the case of dentinogenesis imperfecta (Courtesy Dr Chole).

- **Anterior region**—in the incisor region the crowns tend to more nearly square, but the mesial and distal borders are sometimes curve.
- **Posterior region**—the bicusps and molars are flatter than normal and the normal circumferential curves are accentuated so that the teeth present bulbous appearance. The neck of teeth suddenly narrows down. The appearance of crowns may be described as 'dumpy'.

Shield type II

- Clinical features are same as that of shield type I, except they are somewhat of severe form and it is not associated with osteogenesis imperfecta.

Shield type III

- **Dentition**—both the dentitions are affected.
- **Enamel and dentin**—the thickness of enamel is normal and dentin is very thin.
- **Color and shape**—opalescent color, bell shaped crown and multiple pulp exposure.

Radiographic features

- **Appearance**—constriction of cervical portion of tooth that imparts bullous appearance.
- **Attrition**—there may be slight to marked attrition of teeth.
- **Pulp, root and root canal**—partial or complete obliteration of pulp chamber (**Fig. 9-43**). Pulp obliteration may take place before or after eruption of teeth. Root canals may be absent or thread like or may be blunted.
- **Periapical area**—periapical radiolucency without pulpal involvement and periodontal ligament space widening.
- **Flame shaped pulp canal**—in some cases, the radicular portion of pulp cavities is very narrow, while the pulp chambers have a bulbous expansion terminating in a point deep to the occlusal aspect which resembles 'flame'.
- **Shell teeth**—In Brandywine type, enamel of tooth appears normal, while the dentin is extremely thin and the pulp chambers are enormous. Teeth appear as 'shell teeth'. In addition, root of tooth are extremely short, so it appears as if enamel and dentin surrounded by extremely large pulp chamber and root canals.

Fig. 9-43: Obliteration of pulp chamber seen in dentinogenesis imperfecta (Courtesy Dr Chole).

Diagnosis

- **Clinical diagnosis**—rapid loss of enamel with attrition of tooth. Clinically multiple pulp exposure can be seen.
- **Radiological diagnosis**—obliteration of pulp chamber. Presence of periapical radiolucency without pulpal involvement.

Management

- **Overdenture**—Overdenture should be given and teeth should be covered with fluoride releasing glass ionomer cement.
- **Crown**—cast metal crown in posteriors and jacket crown in anterior can be given.

Dentin Dysplasia

It is a rare disturbance of dentin formation, characterized by normal but atypical dentin formation, with abnormal pulp morphology. It represents as autosomal dominant trait. Some systemic diseases are also manifested as dentin dysplasia features. They are calcinosis cutis, vitaminosis D and tumoral calcinosis.

Classification

According to Shield (clinical)

- Shield type I—dentin dysplasia.
- Shield type II—anomalous dysplasia.

According to Witkop (radiological)

- Radicular dentin dysplasia
- Coronal dentin dysplasia.

Clinical features

Shield type I

- *Synonym*—it is also called as 'rootless teeth', 'non-opalescent and opalescent dentin' and 'radicular dentin dysplasia'.
- *Appearance*—permanent and primary teeth are of normal size, shape and consistency.
- *Color*—affected teeth are occasionally slightly amber and translucent.
- *Mobility*—as the root size is short patient notice mobility of the teeth. There is also premature exfoliation of teeth (Fig. 9-44).
- *Significance*—malalignment and malpositioning due to extreme mobility. Minor trauma may result in exfoliation.

Fig. 9-44: Type I dentin dysplasia showing short root.

Shield type II

- *Color*—significant differences of color in both the dentitions. Primary teeth with yellow, brown, bluish, grey-amber translucent appearances. Permanent teeth of normal color.
- *Root*—root size is normal in size.

Radiographic features

1. Radicular

- *Pulp canals*—pulp chamber and canals are obliterated before eruption and appear as half moon shaped.
- *Roots*—they have short roots with sharp conical and apical constriction. These are abnormally shaped; primary teeth are represented by spicule.
- *Periapical pathology*—multiple periapical radiolucencies are present.
- *Pulp chamber*—obliteration of pulp chamber produce 'crescent or chevron shaped (V shaped line or strip)' pulp remnants.

2. Coronal

- *Thistle tube appearance*—permanent teeth exhibit abnormality, large chamber in coronal portion often described as 'thistle tube' in shape due to radiating extension of pulp chamber.
- *Pulp stone*—teeth show multiple pulp stones.

Diagnosis

- *Clinical diagnosis*—unusual mobility of tooth without periodontal involvement may suspect dentin dysplasia. Radiograph is necessary.
- *Radiological diagnosis*—very short root of the teeth.
- *Laboratory diagnosis*—normal dentinal tubule formation appears to be blocked so that new dentin forms around obstacle and takes the characteristic appearance described as 'lava flowing around boulder'.

Differential Diagnosis

- *Hereditary opalescent dentin*—pulp chamber never fills before eruption in type II dentin dysplasia. Thistle shaped pulp chamber occurs in dentin dysplasia. Teeth in opalescent dentin have bell shaped crown with constriction in cervical region while in dentin dysplasia it is normal. If root is short and narrow it is opalescent dentin, while normal appearing root or no root at all is dentin dysplasia. Periapical rarefaction in association with non-carious tooth is in dentin dysplasia.

Management

- *Oral hygiene*—meticulous oral hygiene should be maintained to avoid early loss of teeth.
- *Retrograde endodontic treatment*—it should be done in patient who have periapical pathology and have a short root.
- *Periapical curettage*—it should be done in cases when there is periapical inflammatory conditions are present.

Regional Odontodysplasia

It is also called as 'odontogenic dysplasia' or 'ghost teeth'. It is an unusual development anomaly in which ectodermal and mesodermal tooth component are affected. It is a

localized arrest in tooth development. In this condition all the elements of tooth are hypocalcified and hypoplastic.

Etiology

It has uncertain etiology. Various factors like trauma, infection, local ischemia, local vascular defect, genetic transmission, local somatic mutation and activation of latent viruses are suggested as etiological agents.

Clinical features

- **Dentition**—deciduous and permanent teeth are involved.
- **Site**—maxillary involved more than mandibular. Most frequently affected are permanent central incisor, lateral incisor and cuspid. Single tooth or several teeth in one quadrant are affected. It may involve both side of midline.
- **Color, shape and size**—affected teeth are small and mottled brown. Shape is irregular with evidence of defective mineralization (**Fig. 9-45**).

Fig. 9-45: Mottled brown discoloration of tooth in regional odontodysplasia.

- **Caries**—affected teeth are susceptible to caries, and prone to fracture.
- **Periapical abscess**—this is frequent finding in regional odontodysplasia. The reason is that discontinuous odontogenic epithelium in the follicle may not completely fuse with oral epithelium which results in invasion of microorganisms in the tooth.
- **Delayed eruption**—there is either delay or total failure of eruption. This occurs as enamel matrix has been shown to induce formation of cementum when it is exposed to extrafollicular tissue. Cementum deposition in crown may retard eruption of teeth.
- **Surface**—surface is rough in feeling
- **Gingival swelling**—gingival swelling adjacent to the tooth surface is common occurrence. The swelling occurs due to calcification in adjacent soft tissue.
- **Associated disease**—this condition may be associated with vascular nevi, hemangioma, hydrocephalus and epidermal nevus syndrome.

Radiographic features

- **Ghost teeth**—there is marked reduction in density, so that the teeth assume ghost appearance. Ghost teeth that do not erupt are so hypomineralized and hypoplastic that they appear to be resorbing.
- **Shell teeth**—sometimes only the shell of enamel remain on the teeth, this appearance is called as shell teeth.
- **Pulp and root**—pulp chamber is very large with wide root canals. Poorly outlined roots are shortened. In some cases, calcification in the pulp is present.

Diagnosis

- **Clinical diagnosis**—irregular shaped teeth with brown discoloration.
- **Radiological diagnosis**—shell teeth appearance seen radiologically.

Differential Diagnosis

Shell teeth of dentinogenesis imperfecta—In dentinogenesis imperfecta, familial involvement in contrast to odontodysplasia. Enamel is not hypoplastic in shell teeth as compared to ghost teeth. Only few teeth are affected in either dentition.

Management

- **Prosthetic replacement**—many suggest to extract involved tooth at the earliest which is followed by prosthetic replacement.
- **Restorative procedure**—in some cases, root canal treatment should be carried out and tooth should be saved.

Environmental Alteration of Tooth

Structure of Teeth

Enamel Hypoplasia

It is an incomplete or defective formation of organic enamel matrix. Local and systemic factors that interfere with the normal matrix formation can cause enamel surface defects and irregularities.

Classification

- **Mild**—there may be only few small grooves, pits and fissures on enamel surface.
- **Moderate**—enamel exhibits rows of deep pits arranged horizontally across the surface.
- **Severe**—considerable portion of enamel may be absent.

Types of environmental hypoplasia

- Hypoplasia due to nutritional deficiency
- Hypoplasia due to exanthematous disease
- Syphilitic hypoplasia
- Hypoplasia due to hypocalcaemia
- Hypoplasia due to birth injury

- Turner hypoplasia
- Dental fluorosis
- Tetracycline hypoplasia.

Hypoplasia due to nutritional deficiency

- *Causes*—it occurs, due to deficiency of vitamin A, C, D, calcium and phosphorus.
- *Age*—2/3rd of this occurs during infancy period or early childhood.
- *Site*—frequently involved are those teeth which are formed within the first year of birth.
- *Pathogenesis*—vitamin D deficiency causes rickettsial phenomenon, resulting from lack of proper calcification of enamel matrix.
- *Appearance*—horizontal pitting occurs in rows, on the teeth undergoing matrix formation at the time of dietary deficiency or during course of febrile episode (**Fig. 9-46**).
- *Color*—pitting characteristically picks up stain and discoloration occurs.

Fig. 9-46: Horizontal pitting seen in anterior region in enamel hypoplasia.

Hypoplasia due to exanthematous disease

- *Causes*—it includes measles, chickenpox and scarlet fever. There is temporary elevation of body temperature.
- *Pathogenesis*—temperature may remain elevated for prolonged period of time and under these circumstances, ameloblasts may be adversely affected.

Syphilitic hypoplasia

- *Site*—it involves maxillary and mandibular permanent incisors and 1st molars. Incisors affected are called as 'Hutchinson incisors' and molar are called as 'mulberry molars' (Moon's molar, Fournier's molar).
- *Hutchinson's incisors*—Upper central incisor is screw driver shaped. Mesial and distal surfaces of crown are tapering and converging towards incisal edge of the tooth, rather than towards cervix. In addition, incisal edge is also notched. The cause behind this is the absence of the central tubercle or calcification center.

- *Mulberry molars*—crown of 1st molar in congenital syphilis is irregular. Enamel of the occlusal surface and occlusal third of the tooth appears to be arranged in agglomerate mass of globule, rather than in well formed cusp. The crown is narrower on occlusal surface, than at the cervical margin.

Hypoplasia due to hypocalcemia

- Tetany induced by decreased level of calcium in the blood, which is as low as 6 to 8 mg per ml.
- As calcium is required for normal tooth formation, there is defective formation of the enamel.
- Enamel hypoplasia, is usually of 'pitting' variety.

Hypoplasia due to birth injury

- *Prenatal*—marked enamel hypoplasia affects incisal 2/3rd of enamel on maxillary primary incisors. It is due to gastrointestinal tract disturbances or metabolic disorders in the fetal life, probably during 2nd and 3rd trimester of pregnancy.
- *Neonatal*—a wide band or line of enamel affects the primary teeth of children associated with premature birth or low birth weight. In traumatic birth, it may affect the process of amelogenesis.

Turner's hypoplasia

- *Turner's tooth*—localized type of hypoplasia is caused by local infection or trauma is called as 'turner's hypoplasia' and that tooth is called as 'turner's tooth'.
- *Pathogenesis*
 - *Local infection*—if deciduous teeth become carious during the period when the crown of succeeding permanent tooth is formed, bacterial infection involving periapical tissues may occur and this may disturb the ameloblastic layer of permanent tooth bud, resulting in hypoplastic crown.
 - *Trauma*—when deciduous teeth have been driven into alveolus and have disturbed the permanent tooth bud and if this permanent tooth bud is still being formed, resulting injury may be manifested as yellowish or brownish stains or pigmentation of enamel, usually on labial surface or as true hypoplastic pitting defect.
- *Site*—most commonly affected teeth are permanent bicuspid as deciduous primary molar are most frequently affected carious tooth in deciduous dentition. Anterior teeth are involved less commonly as their crown is formed before the development of any periapical inflammatory lesion in deciduous anterior region.
- *Appearance*—there may be any degree of hypoplasia, ranging from mild brownish discoloration of enamel to severe pitting and irregularity of the crown. Hypoplastic defect may contain cementum, which may be stained yellowish brown.

Dental fluorosis

Drinking water that contains in excess of 1 PPM (part per million) fluoride can affect the ameloblasts during the tooth formation stage and can cause the clinical entity called as 'mottled enamel'. It is due to disturbance in tooth formation caused by excessive intake of fluoride, during the formative period of dentition.

Pathogenesis

- *Formative stage*—disturbance of ameloblasts during the formative stage of tooth development and higher level of fluorides interfere with the calcification process of matrix.
- *Matrix formation stage*—there is diminished matrix production, change of matrix composition and change in ion transport mechanism.
- *Maturation stage*—in maturation phase, there is retention of amelogenin proteins in the enamel structure leading to formation of hypomineralized enamel.

Classification

- *Questionable changes*—it is characterized by occasional white flecking or spotting of enamel.
- *Mild changes*—it is manifested by white opaque areas involving more of the tooth surface.
- *Moderate and severe changes*—showing pitting and brownish staining of the surface and sometimes even corroded appearance.

Clinical features

- *Dentition*—dental fluorosis in primary dentition is less severe as compared to permanent dentition.
- *Color of teeth*—it frequently becomes stained as unsightly yellow to brown color, which is caused by coloring agents from food, medicine and by disintegration of increase protein contain in the hypomineralized parts of the enamel (**Figs 9-47A and B**).
- *Severe fluorosis*—teeth which are moderately or severely affected may show tendency to wear or even fracture of enamel (**Fig. 9-48**). Sometimes, white patches in enamel may become striated, pitted and mottled.

Clinical classification for fluorosis (TF)

- *Score 0*—the normal translucency of the glossy creamy-white enamel remains after wiping and drying of the surface.
- *Score 1*—thin white opaque lines are seen running across the tooth surface. The lines correspond to the position of perikymata. In some cases 'snow-capping' of cusps may also be seen.
- *Score 2*—the opaque white flecks are more pronounced and frequently merge to form small cloudy areas scattered over the whole surface.
- *Score 3*—merging of the white lines occurs and cloudy areas of opacity occur to spread into many parts of the surface. In between the cloudy area, white lines can also be seen.

Figs 9-47A and B: Mild type fluorosis seen in anterior region.

Fig. 9-48: Severe type of dental fluorosis showing fracture of enamel in anterior region (Courtesy Dr Chole).

- *Score 4*—the entire surface exhibits a marked opacity or appears chalky white.
- *Score 5*—the entire surface is opaque and there are round pits that are less than 2 mm in diameter.

- **Score 6**—the small pits may frequently be seen merging in the opaque enamel to form bands that are less than 2 mm in vertical height.
- **Score 7**—there is loss of the outermost enamel in irregular areas and less than half of surface is involved.
- **Score 8**—the loss of the outermost enamel involves more than half of the enamel. The remaining intact enamel is opaque.
- **Score 9**—the loss of the major part of outer enamel results in change in anatomic shape of the surface. A cervical rim of opaque enamel is often noted.

Radiographic features

- **Mild form**—when there is slight depression or pit on the mesial or distal borders of the crown, it is apparent on a radiograph. When there is depression on lingual or labial surface, it may be gone unnoticed or present as slightly increased darkness.
- **Moderate form**—more extensive lesion appears as a series of rounded dark shadows crossing the tooth in straight lines.
- **Severe form**—very gross deformity produces a crown that is markedly shriveled at its incisal and occlusal surfaces. Such teeth may be presented as small spikes of dental tissue arising from a short stunted base.

Tetracycline hypoplasia

- **Pathogenesis**—it may be incorporated in calcifying enamel matrix by formation of a tetracycline calcium orthophosphate complex.
- **Color of teeth**—after teeth eruption and exposure to sunlight, discoloration may result, ranging from light yellow to brown (**Fig. 9-49**). Varying degree of hypocalcification may also exist.
- **Prevention**—tetracycline should not be administered during pregnancy and until the child become 8 years old.

Fig. 9-49: Hypoplasia of yellow to brown color in upper anterior region due to tetracycline staining.

Management of enamel hypoplasia

- **Restoration**—the hypoplastic teeth are more susceptible to dental caries than the normal teeth. The restoration is usually confined to area of involvement.
- **Crown**—Chrome steel crown is given in case of severe hypoplasia. Severe forms require composite restoration or full ceramic crown.
- **Bleaching with 30% H₂O₂** (hydrogen peroxide)—this technique is enhanced by microabrasion or grinding of the surface layer.
- **Calcium sucrose phosphate gel**—treatment involves cleaning of the affected teeth with pumice and glycerin, rinsing with water and applying 37% phosphoric acid for 1½ or 2 minutes. The treatment is repeated followed by application of 2% sodium fluoride for 4 minute. Finally, a thick layer of 40% calcium sucrose gel is placed on the affected teeth. The patient was instructed not to rinse or eat for 30 minutes.
- **Desensitizing paste**—it should be used to decrease the sensitivity of teeth which may be due to exposed dentin.

Disturbance in Eruption

Premature Eruption

The eruption of teeth may occur before their normal eruption time. In some cases tooth may be present as natal teeth and neonatal teeth.

Etiology

- **Familial pattern**—this can be occurred as familial disease.
- **Endocrine disorders**—secretion of several endocrine organs like thyroid, adrenals and gonads may alter the eruption rate of teeth. It can also be occurred in adrenogenital syndrome.

Clinical features

- **Sites**—usually only one or two teeth erupt early, mostly deciduous and mandibular central incisors.
- **Symptoms**—they are often well formed and normal in all aspects, except they may be mobile.
- **Premature loss of deciduous teeth**—premature loss of deciduous teeth may give rise to premature eruption of permanent teeth.

Delayed Eruption

In some cases eruption may be delayed. It may occur due to various conditions.

Etiology

- **Systemic conditions**—like rickets, cretinism and cleidocranial dysplasia.
- **Local factors**—like fibromatosis gingiva in which dense connective tissue does not permit the eruption of teeth.

Clinical features

- *Partially impacted teeth*—individual permanent teeth are observed to be delayed in eruption. There may be partially impacted permanent teeth.
- *Deviation in eruption path*—there is deviation in the eruption path of teeth.
- *Pseudoanodontia*—patients may suffer from pseudoanodontia.

Management

- *Extraction of teeth and space maintainer*—extract the primary teeth and use space maintainers until the permanent tooth erupts.

Embedded and Impacted Teeth

Embedded teeth are those which are unerupted, usually because of lack of eruptive force.

Impacted teeth are those prevented from erupting by some physical barrier in eruption path.

Etiology

- *Lack of space*—lack of space due to crowding of dental arch and premature loss of deciduous teeth with subsequent partial closure of the spaces they occupied.
- *Rotation*—rotation of tooth bud result in teeth which are aimed at wrong direction because their axis is not parallel to normal eruption path.
- *Systemic disease*—like osteopetrosis, ectodermal dysplasia, cleidocranial dysostosis, rickets and cretinism can be associated with impactions.
- *Cyst and tumors*—in case of overlying cyst and tumors, teeth may fail to erupt in oral cavity.
- *Trauma*—in some cases trauma may cause impaction of tooth.

Clinical features

- *Site*—most commonly affected teeth are maxillary and mandibular third molars and maxillary cuspids (Fig. 9-50), followed by the premolars and supernumerary teeth. Teeth may be impacted distally, mesially, horizontally etc.
- *Significance*
 - Dentigerous cyst may be associated with impacted teeth and may cause of impacted teeth and destruction of bone.
 - Periodontal pocket formation and subsequent infections may occur.
 - Because of location, impacted tooth may cause resorption of roots of adjacent teeth.
 - There may be periodic pain and trismus when infection occurs around the partially impacted teeth.
 - Referred pain from impacted teeth is also been described.

- In some cases, development of pathologic conditions like cyst and tumors can occur.

Fig. 9-50: Inverted impacted canine seen in maxillary region.

Impacted mandibular third molar

It may exhibit variety of positions and is classified by Winter as (Fig. 9-51):

Fig. 9-51: Different types of impaction (diagrammatic representation).

- *Mesioangular impaction*—it lies oblique in bone, the crown pointing in a mesial direction, usually in contact with the distal surface of the root or crown of the second molar (Fig. 9-52).
- *Distoangular impaction*—the third molar lies oblique in the bone, the crown of the tooth pointing distally towards the ramus, the roots are approximate to the distal root of second molars.
- *Vertical impaction*—the third molar is in its normal vertical position but it prevented from erupting by impingement on the distal surface of the second molar or the anterior border of ramus.

Fig. 9-52: Mesioangular impacted of mandibular right and left third molar (Courtesy Dr Parate).

- **Horizontal impaction**—the third molar is in horizontal position with respect to the body of mandible and the crown may, or may not be in contact with the distal surface of the second molar crown or root.

Radiographic assessment of mandibular third molars

- **General**—the main features to be examined include angulations, crown, root, the relationship of the apices with the inferior dental canal, the depth of the tooth in the alveolar bone and buccal and lingual obliquity.
- **Crown**—in crown, you should look for the size, shape, extent of caries and severity of resorption.
- **Root**—in roots, you should note the number, shape, curvature; whether they are favorable or unfavorable and the stage of development.
- **Relationship between canal and root**—the apices of lower 3rd molar often appear close to the inferior dental canal. The roots may be grooved by canal or rarely, tunnel through it (Fig. 9-53).

Fig. 9-53: Different types of relationships between canal and roots.

• Tramlines (Fig. 9-54)

- **Normal appearance**—the normal radiographic appearance of canal is too thin radiopaque line called as 'tramlines', which are evident across the root.
- **Loss of tramline**—if there is loss of tramline, then root and canal are in contact.
- **Narrowing of tramline**—if there is narrowing of the tramline, then lingual aspect of root is grooved by the canal.

- **Alteration in direction**—if there is alteration in direction of canal at root apex, then the apex of root is grooved by canal.
- **Radiolucent band in canal**—if there is radiolucent band across the root, the root tunneled through by the canal.

Fig. 9-54: Different types of tramlines appearance seen.

- **Assessment of tooth depth**—two main methods are used commonly to assess the tooth depth i.e. 'winter's line' and using the roots of the second molar as a guide.
- **Winter's line**—in this method, there are three imaginary lines (described by number or color) on a geometrically accurate periapical radiograph (Fig. 9-55).
 - **White line**—the line or white line is drawn along the occlusal surface of the erupted first 1st and 2nd molars.
 - **Amber line**—the second or amber line is drawn along the crest of the interdental bone between the 1st and

Fig. 9-55: Application of Winter's line to impacted third molar.

2nd molars, extending distally along the internal oblique ridge. This line indicates the margins of the alveolar bone surrounding the tooth.

- **Red line**—the third line or red line is a perpendicular dropped from the white line to the point of application of elevator, but it is measured from the amber line to this point of application of elevator. This line measures the depth of third molar within the mandible. As a general rule, if the red line is 5 mm or more in length, the extraction is considered to be sufficiently difficult.
- **Using the roots of second molars as a guide**—in this, the roots of the adjacent second molar are divided horizontally into three parts. A horizontal line is drawn from the point of application for an elevator to the second molar. If the point of application lies opposite the coronal, middle or apical third, the extraction assesses is classified as being easy, moderate or difficult.
- **Bone**—after this, assessment of surrounding bone is done and checked for the anteroposterior position of the ascending ramus, determine the access to tooth and amount of overlying bone, the texture and density of bone and evidence of previous pericoronal infections.

Management

- **Surgical exposure**—it depends upon the tooth involved. In some cases, like in maxillary cuspids, orthodontic treatment with surgical exposure can be done to bring the tooth in normal occlusion.
- **Surgical removal**—it is done when impacted tooth is causing problems to the patient.
- **Complication**—it includes transient and permanent sensory loss, alveolitis, trismus, infection, fracture, periodontal injury and injury to adjacent teeth.

Ankylosis or Submerged Teeth

Submerged teeth are deciduous teeth that have undergone variable degree of root resorption and then have become ankylosed to bone. Ankylosis of the teeth should be considered as interruption in rhythm of eruption. Ankylosis occurs due to anatomic fusion of cementum or dentin with alveolar bone. Unerupted permanent teeth may become ankylosed by enostosis of enamel.

Etiology

- **Familial pattern**—observations of ankylosed teeth in the same family are very frequent.
- **Changes in local metabolism**—this will lead to ankylosis of tooth in some cases.
- **Trauma**—trauma may cause disruption of periodontal ligament which act as natural barrier between cementum and bone and which prevent osteoblasts from applying bone directly to the cementum.
- **Infection**—some infections may disrupt the normal eruption pathway resulting in ankylosis of tooth.

- **Abnormal tongue pressure**—abnormal tongue pressure may lead to ankylosis of tooth.
- **Other cause**—other causes of ankylosis are chemical and thermal irritation, local failure of bone growth, injury.

Clinical features

- **Age**—it is more commonly found in the second decade of life.
- **Site**—most commonly affected teeth are mandibular deciduous first molars, followed by anterior teeth. Patient who has one or two ankylosed teeth is more likely to have other teeth to be ankylosed.
- **Infra-occlusion**—gradual loss of occlusal plane as the tooth is submerged below the level of occlusion.
- **Delayed eruption of permanent teeth**—exfoliation and subsequent replacement by permanent teeth is prevented due to ankylosis.
- **Lack of mobility**—affected teeth lack mobility even after root resorption.
- **Percussion**—it produces characteristic solid sound in contrast to dull, cushioned sound of normal teeth on percussion.
- **Significance**—development of malocclusion, local periodontal disturbances and dental caries occurs.

Radiographic features

- **Absent periodontal ligament space**—partial absence of periodontal ligament. A break in continuity of periodontal ligament, indicating an area of ankylosis, is usually evident (**Fig. 9-56**).

Fig. 9-56: Ankylosis of third molar showing absence of periodontal ligament space.

Management

- **Surgical excision**—keep tooth under observation. If required, surgical excision is carried out.

Transposition

Tooth may be found occupying an unusual position in relation to other teeth, in the dental arch, i.e. two teeth apparently exchanging their position.

Clinical features

- **Location**—permanent canine is most often involved, with its position interchange with lateral incisor. Second premolar is infrequently found between first and second molar. Transposition of central and lateral incisor is rare. Transposition does not occur in primary dentition (Figs 9-57A and B).

Figs 9-57A and B: Transposition of canine occur with premolar in maxillary left region.

Radiographic features

- It can be recognized on radiograph by the unusual sequence of teeth in dental arch (Fig. 9-58).

Management

These teeth can be prosthetically altered to improve function and esthetics.

Eruption Sequestrum

As the molar teeth erupt through bone, they will occasionally separate small osseous fragments of bone like corkscrew. If bony spicule is large or eruption is fast, complete resorption of bone cannot occur.

Fig. 9-58: Transposition of canine with premolar in maxillary region.

Clinical features

- **Location**—it is a tiny irregular spicule of nonviable bone overlying the crown of an erupting permanent molar. Spicule directly overlies the central occlusal fossa, but is contained within the soft tissues.
- **Signs**—as the tooth continues to erupt, the cusps emerge and the fragments of bone completely sequester through mucosa and are then lost.
- **Symptoms**—child may complain of slight soreness produced by compression of soft tissues over the spicule, by the movement of the spicule in the soft tissue crypt during mastication and following eruption through mucosa.

Radiographic features

- It appears as a tiny irregular opacity overlying the central occlusal fossa, but separated from the tooth itself.

Management

- Removal of spicule, if necessary.

Ectopic Eruption

In this condition, eruption of the teeth does not occur at normal location.

Etiology

- **Large size of teeth**—if the tooth is larger than the normal mean size of all maxillary primary and permanent teeth then chances of ectopic eruption increases.
- **Small jaw size**—smaller maxilla or posterior positioning of maxilla in relation to the cranial base can also lead to ectopic eruption.
- **Local factors**—abnormal angulation and delayed calcification.

Clinical features

- **Age and sex**—it occurs most frequently in boys than girls.

- **Location**—position of teeth can be seen lingually to the normal location (Fig. 9-59).
- **Root resorption**—eruption of permanent 1st molar into roots of primary 2nd molar may cause destruction of distal root of maxillary 2nd molar.
- **Exfoliation**—it may become hopelessly locked and produce premature exfoliation.

Fig. 9-59: Mandibular central incisor seen more lingually than its normal location.

Management

Brass looped wires in contact area should be given.

Premature Exfoliation

Etiology

- **Syndrome**—it is seen in Papillon-Lefèvre syndrome.
- **Hereditary**—it occurs in familial juvenile periodontitis and familial fibrous dysplasia.
- **Nutritional disorders**—like hypophosphatasia and cyclic neutropenia.
- **Others**—histiocytosis and acrodynia.

Clinical features

- **Bone loss**—there is widespread loss of supporting alveolar bone.
- **Teeth**—loosening, migration and spontaneous loss of teeth (Fig. 9-60).

Management

No treatment, except to correct the etiological factors.

Loss of Tooth Structure

Attrition

It is the physiologic wearing away of teeth because of tooth-to-tooth contact, as in mastication. It plays an important physiological role as it helps to maintain an advantageous crown-root ratio and gains intercoronal space of 1 cm, which facilitates third molar eruption. Attrition can be

Fig. 9-60: Early exfoliation seen in deciduous tooth (Courtesy Dr Shetty).

considered pathological when it cause functional, esthetics and dental sensitivity problems.

Types

- **Physiological attrition**—attrition which occurs due to normal aging process, due to mastication.
- **Pathological attrition**—it occurs due to certain abnormalities in occlusion, chewing pattern or due to some structural defects in teeth.

Etiological factors for pathological attrition

- **Abnormal occlusion**
 - **Development**—malocclusion and crowning of teeth, may lead to traumatic contact during chewing, which may lead to more tooth wear.
 - **Acquired**—due to extraction of teeth. Extraction causes increased occlusal load on the remaining teeth, as the chewing force for the individual remains constant.
 - **Premature contact**—in case of edge-to-edge contact, pathological attrition can also occur.
- **Abnormal chewing habits**—parafunctional chewing habit like bruxism and chronic persistent chewing of coarse and abrasive food or other substances like tobacco.
- **Occupation**—in certain occupations, workers are exposed to an atmosphere of abrasive dust and cannot avoid it getting into mouth.
- **Structural defect**—in defects like amelogenesis imperfecta and dentinogenesis imperfecta, hardness of enamel and dentin is reduced and such teeth become more prone to attrition.

Clinical features

- **Sex**—men usually exhibit more severe attrition than women due to greater masticatory forces.
- **Sites**—it may be seen in deciduous as well as permanent dentition. It occurs only on occlusal, incisal and proximal surfaces of teeth. Severe attrition is seldomly seen in primary teeth, as they are not retained for any great period. Palabal cusps of maxillary teeth and buccal cusps of mandibular posterior teeth show most wear.

- *Appearance*—the first clinical manifestation of attrition is the appearance of small polished facet on a cusp tip or ridge and slight flattening of an incisal edge.
- *Physiological attrition*
 - *Onset*—physiological attrition begins with wearing of the incisal edge of an incisor, which is followed by the palatal cusp of maxillary molars and buccal cusp of mandibular molars. It commences at the time of contact or occlusion. Physiological tooth surface loss results in a reduction, in both vertical tooth height and horizontal tooth width (**Fig. 9-61**).

Fig. 9-61: Physiological attrition showing wearing of the occlusal surface of the molar teeth.

- *Contact points*—due to slight mobility of teeth in their socket (which is a manifestation of resiliency of periodontal ligament) similar facets occur at contact points.
- *Color of teeth*—when the dentin gets exposed, it generally becomes discolored i.e. brown in color.
- *Signs*—there is gradual reduction in cusp height and consequent flattening of occlusal inclined plane. There is shortening of the length of dental arch, due to reduction in the mesiodistal diameter of teeth. Secondary dentin deposition occurs.
- *Pathological attrition*
 - *Severe tooth loss*—in pathological attrition severe tooth loss is seen (**Fig. 9-62**).
 - *Dentoalveolar compensation*—if attrition affecting the occlusal surfaces of teeth has occurred, then reduction in occlusal face height (vertical dimension of occlusion) and increase in the freeway space could be anticipated. This may be further complicated by forward posturing of mandible. It is often observed, however, that despite overall tooth surface loss, the freeway space and the resting facial height appear to remain unaltered primarily because of dentoalveolar

compensation. This is important with respect to patient assessment. If restoration of worn teeth is being planned then the extent of dentoalveolar compensation would appear to determine the dentist's strategy; defining the need to carry out measures such as crown lengthening, to ensure the same vertical dimension of occlusion and freeway space.

Fig. 9-62: Pathological attrition showing severe tooth loss in anterior region.

Radiographic features

- *Crown*—smooth wearing of incisal and occlusal surfaces of involved teeth is evident by shortened crown image (**Fig. 9-63**).
- *Pulp*—sclerosis of pulp chamber and canals is seen due to deposition of secondary dentin which narrows the pulp canals.
- *Periodontal ligament*—widening of periodontal ligament space and hypercementosis.
- *Alveolar bone*—some loss of alveolar bone.

Fig. 9-63: Severe attrition of teeth showing reduced crown length.

Management

- *Modifying factors*—treatment of patient depends upon degree of wear relative to the age of patient, etiology, symptoms and patient's desire.
- *Habit breaking appliance*—the provision of one of three different sorts of splints could be considered. A soft bite guard can help in breaking a bruxist habit or simply will protect the teeth during the bruxist habit. A localized occlusal interference splint is designed to break the bruxist habit and can be worn easily during the day. A stabilization splint reduces bruxism by providing an ideal occlusion: it also enables the clinician to locate and record centric relation. In case of bruxism, use of night guards may be effective in reducing attrition.
- *Corrective method*—correction of malocclusion, stoppage of tobacco chewing habit and restriction of diet to non coarse food are useful in avoiding attrition.
- *Management of sensitivity and esthetics*—non-caries loss of tooth tissue may require treatment for sensitivity, esthetics, function and space loss in the vertical dimension.

Abrasion

It is the pathological wearing away of tooth substance through abnormal mechanical process caused by external agents. In case of tooth wear which is accelerated by chewing an abrasive substance between opposing teeth, exhibits a features of attrition and abrasion. This is called as *demastication*.

Etiology

- *Abrasive dentifrices*—use of *abrasive dentifrices* can lead to abrasion of the incisal surface.
- *Habitual*—Habitual pipe smoker may develop abrasion on the incisal edges of lower and upper anterior teeth. In some cases habitual opening of bobby pins may lead to abrasion.
- *Horizontal tooth brushing*—horizontal tooth brushing may lead to abrasion of the cervical area of teeth.
- *Occupational*—it occurs when objects and instrument are habitually held between the teeth by people during working. *Holding nails* or *pins* between teeth e.g. in carpenters, shoemakers or tailors.
- *Dental floss or tooth picks injury*—improper use of dental floss and tooth picks.
- *Ritual abrasion*—it is mainly seen in Africa.

Clinical features

Tooth brush injury

- *Sites*—it usually occurs on exposed surfaces of roots of teeth. It is more commonly seen on left side of right handed persons and vice versa.

- *Mechanism*—it occurs due to back and forth movement of brush with heavy pressure causing bristles to assume wedge shaped arrangement between crown and root.
- *Appearance*—in horizontal brushing there is usually a 'V' shaped or 'wedge' shaped ditch on the root at cemento enamel junction (**Fig. 9-64**). It is limited coronally by enamel.

Fig. 9-64: Wedge shaped ditch seen in the cervical area of anterior teeth.

- *Symptoms*—patient develops sensitivity as dentin becomes exposed.
- *Signs*—the angle formed in the depth of the lesion as well as that of enamel edge is a sharp one. Cervical lesions caused purely by abrasion have sharply defined margins and a smooth, hard surface. The lesion may become more rounded and shallow, if there is an element of erosion present.
- *Dentinal features*—exposed dentin appears highly polished (**Fig. 9-65**). Exposure of dentinal tubules and

Fig. 9-65: Exposed dentin is seen as highly polished surface.

consequent irritation of the odontoblastic processes stimulates secondary dentin formation which is sufficient to protect the pulp from clinical exposure.

Dental floss or tooth pick injury

- **Site**—Cervical portion of proximal surfaces, just above the gingival margin, is affected. Grooves on distal surface are deeper than on mesial surface (Fig. 9-66).

Fig. 9-66: Abrasion seen on the proximal surface of the patient due to dental floss injury.

Radiographic features

Tooth brush injury

- **Location**—radiolucent defect at the cervical level of teeth.
- **Shape**—well defined semilunar shape, with borders of increasing density (Fig. 9-67).
- **Pulp**—pulp chamber may be partially or fully sclerosed in severely affected teeth.

Dental floss injury

- **Appearance**—narrow semilunar grooves in the interproximal surfaces of teeth near cervical area.

Fig. 9-67: Semilunar defect seen at the cervical area of anterior teeth.

Management

- **Modified teeth cleaning habits**—modification of teeth cleaning habits will be indicated.
- **Removal of cause**—elimination of causative agent should be carried out.
- **Restoration**—restoration should be done for esthetics purpose and to prevent further tooth wear.

Erosion

It is the loss of tooth substance by chemical process that does not involve known bacterial action. Dissolution of mineralized tooth structure occurs due to contact with acids. Erosion is a chemical process in which the tooth surface is removed in the absence of plaque.

Types (depending upon etiology)

- **Intrinsic**—erosion that occur due to intrinsic causes e.g. gastroesophageal reflux, vomiting.
- **Extrinsic**—erosion occurring from extrinsic sources e.g. acidic beverages, citrus fruits.

Etiology

- **Local acidosis**—it is seen in periodontal tissue from damage due to traumatogenic occlusion.
- **Chronic vomiting**—complete loss of enamel on lingual surfaces of teeth through dissolution by gastric hydrochloric acid. Vomiting can also occur in alcoholics, peptic ulcer, gastritis, pregnancy and drug side effect.
- **Acidic foods and beverages**—Large quantities of highly acidic carbonated beverages or lemon juice can produce erosion. Most of the fruits and fruits juices have a low pH and can cause erosion. Frequent consumption of carbonated drinks, which are acidic in nature, may result in the erosion of teeth.
- **Anorexia nervosa**—it induces chronic vomiting often after bouts of uncontrolled eating that is interspersed between periods of starvation, because of inner rejection of food.
- **Occupational**—workers involving in manufacturing of lead batteries, sanitary cleaners or soft drinks can develop erosion.
- **Poorly monitored pH swimming pool**—in cases of poorly monitored pH swimming can also cause erosion of the teeth.
- **Medication**—medication like chewable vitamin C and aspirin tablet may lead to erosion of teeth.

Clinical features

- **Sites**—It occurs most frequently on labial and buccal surfaces of teeth; some times, may occur on proximal surfaces of teeth. Usually confined to gingival thirds of labial surface of anterior teeth. Erosion may involve several teeth of dentition. From extrinsic source, it causes erosion on labial and buccal surface and from intrinsic source, it causes erosion on lingual or palatal source.

- *Appearance*—it is usually a smooth lesion which exhibits no chalkiness.
- *Symptoms*—loss of enamel often causes hypersensitivity in teeth and may also trigger secondary dentin formation.
- *Signs*—loss of tooth substance is manifested by shallow, broad, smooth, highly polished and scooped out depression on enamel surface adjacent to cemento-enamel junction. When erosion affects the palatal surfaces of upper maxillary teeth, there is often a central area of exposed dentine surrounded by a border of unaffected enamel. In most cases, it results in little more than a loss of normal enamel contour, but in severe cases, dentin or pulp may be damaged.
- *Pink spot*—there may be pink spot on tooth which is attributable to the reduced thickness of enamel and dentin making the pink hue of pulp visible.
- *Cupping*—erosive lesions cause 'cupping' in dentin.

Radiographic features

- It appears as radiolucent defect in the crown margins may be well defined or diffuse.

Management

- *Diet control*—in a patient where loss of tooth surface is essentially caused by erosive fluids, advise regarding diet and use of sugar free chewing gum.
- *Fluoride mouthwash*—prescription of a fluoride mouthwash is certainly indicated here.
- *Brushing habits*—brushing habits should be modified.
- *Restoration*—restoration of the defect, usually by glass ionomer cement.
- *Systemic management*—for systemic management of vomiting, patient should be referred to the physician.

Abfraction

It is also called as 'stress lesion'. It is the loss of tooth structure that results from flexure which is caused by occlusal stresses. The magnitude of tooth tissue loss depends on the size, duration, direction, frequency and location of the forces.

Causes and mechanism

- *Eccentric forces*—it has been suggested that the stress lesion or abfraction is a consequence of eccentric forces on the natural dentition. In this case when occlusal force is applied eccentrically on the tooth, it gets concentrated at the cervical margin of the tooth. This will cause flexure which causes stress at the cervical fulcrum and results in loss of the overlying tooth structure. Thus this theory propounds tooth fatigue, flexure and deformation via biomechanical loading of the tooth structure, primarily at the cervical region.

- *Occlusal restoration*—some suggested that occlusal restoration may lead to weakening of tooth ability to resist the stresses of occlusion leading to abfraction.
- *Predisposing factors*—factors, such as erosion and abrasion may play a significant role in tooth tissue loss.

Clinical features

- *Location*—it usually affects buccal/labial cervical areas of teeth. Commonly affects single teeth with excursive interferences or eccentric occlusal loads.
- *Appearance*—it appears as deep, narrow V-shaped notch. The lesion is typically wedge shaped with sharp line angles, but occlusal abfraction may present as circular invaginations.

Resorption of Teeth

It is a chronic progressive damage or loss of tooth structure due to the action of cells called odontoclasts. It can be *physiological* as in case of root resorption of deciduous teeth or *pathological*, which occurs in permanent teeth. Pathological resorption may be *external* or *internal*. In external resorption odontoclasts are located in periodontal ligament and in case of internal resorption cells are located in the dental pulp.

External Resorption

It is lytic process occurring in the cementum or cementum and dentin of the roots of teeth.

Types

- *External resorption*—resorption occurring at the apex or along the lateral surface of the roots.
- *External internal resorption*—in this external resorption is very severe and it leads to involvement of pulp.

Etiology

- *Periapical infection*—periapical granuloma (arising due to pulpal infection or trauma), causes subsequent resorption of root apex. On the radiograph, it appears as slight raggedness or blunting of the root apex in the early stages.
- *Reimplanted teeth*—It may result in severe resorption of root. Tooth root is resorbed and replaced by bone which produces ankylosis. Many implanted teeth exhibit complex resorption of root and are gradually exfoliated.
- *Tumors and cysts*—resorption due to tumors and cysts appears to be essentially by pressure phenomenon. In most cases, tissue is present between the tumor and the tooth and it is from this tissue, cells chiefly osteoclasts arise and initiated root resorption. Cysts like apical periodontal cyst may exert such pressure on the apex of tooth the intervening connective tissue may in turn get stimulated for osteoclasts formation and thus, resorption

begins. The apex may be lost leaving a flat or scalloped surface at the distal end of the root.

- *Excessive mechanical and occlusal forces*—usually, due to the force that is applied during orthodontic treatment, the patient exhibits multiple areas of root resorption, irrespective of the manner of treatment. Pressure from occlusal forces results in destruction, primarily of bone, then small lacunae often appear on the surface of cementum and ultimately, it extends into the dentin.
- *Impacted teeth*—teeth which are completely impacted or embedded in the bone, occasionally, will undergo resorption of the crown and root. Impacted tooth may cause resorption of roots of adjacent teeth without itself getting resorbed. This is commonly seen in case of horizontally or mesioangularly impacted mandibular 3rd molars impinging on roots of 2nd molar.
- *Overhanged root canal filling material*—in such cases not only the apex get resorbed but more or less, sides of the root are affected. In some cases, all or most of the roots disappear and the regenerating bone eventually embraces the root canal filling intimately, so that it appears as if the crown of the tooth is held in position by the root filling.
- *Idiopathic*—in this case, burrowing type of external resorption can occur which is usually seen in relation with single or multiple erupted teeth.
- *Other causes*—other factors which may cause external resorption are dental trauma, grafting of alveolar clefts, hormonal imbalance, intracoronary bleaching of pulpless teeth, Paget's disease and periodontal treatment.

Clinical features

- *Sites*—the most frequent site for external resorption is upper incisors, upper and lower bicusps.
- *Symptoms*—the affected tooth is usually asymptomatic.
- *Signs*—When the root is completely resorbed, the tooth may become mobile. If root resorption is followed by ankylosis then the tooth is immobile, in infraocclusion and with high percussion sound.

Radiographic features

External resorption

- *Appearance*—when the lesion begins at the apex, it causes smooth resorption of the root surface. The conical end is removed and replaced by more or less blunt or usually square apex (**Fig. 9-68**).
- *Bone and lamina dura*—bone and lamina dura show normal appearance. It appears as concave and ragged area on the root surface.
- *Lateral external resorption*—if it involves lateral aspect of the tooth, the lesion will be irregular.

Fig. 9-68: External resorption showing blunt apex of molars teeth.

External-internal resorption

- It appears as eccentrically shaped notch with areas of resorption which are uneven and appears like trabeculae. The resorptions extend apically into pulp or coronally under the enamel. This is also called as invasive cervical resorption.

Differential Diagnosis

- *Internal resorption*—in external resorption, the radiograph shows blunting of the apex, a ragged area, a scooped out area on the side of the root. In internal resorption, one can see root canal with well demarcated enlarged ballooning area of resorption. It appears as expansion of pulp chamber and canals. We can also use SLOB technique for the diagnosis of external resorption. In this, external resorption appear to be shift away from the pulp if the angulation moves mesially.
- *Incomplete root formation*—in this, incomplete canal diverges; whereas in external resorption, they usually converge.
- *Short root*—it has conical apex and the root canal is usually not visible at the extreme apex nor is the foramen.
- *Apicectomy*—it reveals evidence of root filling and the history is available.
- *Foreshortening of root*—despite the short root, the canal at the apical end cannot be seen and neither can be the foramen.

Management

- *Removal of cause*—this is most important management of external resorption.
- *Apicoectomy*—it should be carried out to save the tooth.
- *Curettage and filling*—if the area is broad and on lateral surface, curettage and filling of resorbed area should be carried out.

Internal Resorption

It begins certainly in the tooth. It is a condition starting in the pulp, in which the pulp chamber or the root canals or both, of the tooth expand by resorption of the surrounding dentin.

Mechanism

- Precipitating factor → vascular changes in pulp → inflammation and production of granulation tissue → metaplasia of embryonic connective tissue and macrophages → odontoclasts like giant multinucleated cells → resorption of internal wall of pulp.

Etiology

- *Idiopathic*—in this no factors is found to explain the internal resorption.
- *Inflammatory*—inflammatory hyperplasia of the pulp (pulp polyps) may lead to internal resorption of tooth.
- *Pulpal treatment*—pulpal treatment like direct and indirect pulp capping and pulpotomy may stimulate the odontoclasts formation leading to internal resorption.
- *Other causes*—other causes like enamel invagination and acute trauma to teeth may also be responsible for internal resorption.

Types

- *Internal inflammatory resorption*—it occurs due to intense inflammatory reaction within the pulp tissue. In this resorbed dentin is replaced by inflamed granulation tissue.
- *Internal replacement or metaplastic resorption*—it occurs due to absence of any inflammatory reaction within the pulp. In this, pulpal and dentinal walls are resorbed and replaced by bone or cementum like bone.

Clinical features

- *Age and sex*—it occurs during 4th and 5th decades of life and is more common in males.
- *Sites*—it may affect any tooth in primary and secondary dentitions, with prevalence in permanent dentition. It is more common in central incisor, lateral incisors, premolar and canine and 3rd molar according to decreasing frequency. Multiple tooth involvement may be there.
- *Symptoms*—it is asymptomatic and discovered through routine radiographic examination.
- *Pink tooth of mummery*—appearance of pink hued area on the crown of tooth, which represents hyperplastic pulp tissue filling the resorbed area and showing through the remaining overlying tooth substance (**Figs 9-69A and B**). It is called as *pink tooth mummery*.
- *Signs*—when the lesion is located in the crown of teeth, it may expand to such an extent that the crown shows

Figs 9-69A and B: Pink tooth appearance seen in cases of internal resorption of tooth in upper anterior region.

dark shadow due to necrosis of the pulp tissue. If the resorption is in the root, it may weaken the tooth and result in fracture of the tooth.

- *Infectious pulpitis*—it may perforate the crown with hemorrhagic tissue projecting from the perforation and result in infectious pulpitis.

Radiographic features

- *Location*—the destruction may be symmetrically situated around the original canal or it may be eccentric, so that it is situated entirely on one side of the root.
- *Appearance*—radiolucency is homogenous without bony trabeculation or radiopaque foci.
- *Pulp canal*—there is enlargement of canal which may be symmetrical or irregular (**Fig. 9-70**).
- *Shape*—the tooth substance which is destroyed in the root may assume any shape; rounded oval, inverted, pear or irregular (**Fig. 9-71**).
- *Margins*—the margins of enlarged chamber are sharp and clearly defined

Fig. 9-70: Internal resorption in the root showing widening of canal.

Fig. 9-71: Oval-shaped radiolucency in the pulp of internal resorption (Courtesy Dr Mody).

Differential Diagnosis

- *Dental caries*—caries lesion show more diffused margins than internal root resorption. In most cases of internal resorption, enamel is not involved. So, there is no evidence of external orifice.
- *External resorption*—described above

Management

- *Endodontic treatment*—extirpation of pulp with routine endodontic treatment or retrograde filling stops the internal resorption process.
- *Extraction*—extraction of the tooth, if perforation occurs.

Discoloration of Teeth

The color of teeth ranges from yellowish to grayish-white depending on enamel translucency. Discoloration defined

as any change in color or any departure from normal color. Color of teeth becomes darker with age due to increased amount of dentin formation, loss of enamel and staining.

Types

- *Extrinsic*—it occurs due to surface accumulation of exogenous pigment like stains, restorative material, nasmyth membrane, tea, tobacco, iron, medication and chromogenic bacteria.
- *Intrinsic*—it is due to stains within enamel and dentin because of deposition of certain substances. Examples of intrinsic discoloration are amelogenesis imperfecta, dentinogenesis imperfecta, dental fluorosis, porphyria, trauma, medication, ochronosis and hyperbilirubinemia.

Classification

Changes that occur solely in structure and thickness of dental hard tissues:

- *Disturbances of dental hard tissue*
 - Dentinogenesis imperfecta
 - Dental fluorosis
 - Enamel opacities
- Physiologic color changes due to age
- Obliteration of pulp chamber
- Internal resorption
- Initial enamel caries

Discoloration caused by coloring agents taken up by dental hard tissue:

- *During formation*
 - Erythroblastic fetalis
 - Neonatal hepatitis
 - Congenital defect in the bile duct
 - Tetracycline administration
 - Congenital heart disease
- *After eruption*
 - *Endogenous*
 - Necrosis of pulp
 - Hemorrhage of pulp
 - *Exogenous*
 - Amelogenesis imperfecta
 - Turner tooth
 - Dental caries
 - Denudation of dentin
 - Attrition, abrasion and erosion

Various Discoloring Agents

- Food and drink
- Tobacco
- Betel nut
- Restorative materials
- Medicaments like silver, nitrate, tin, iron and iodine
- Blood pigments like hemosiderin, bilirubin and biliverdin
- Products from decomposition of materials.

Causes

Many of the diseases which can cause discoloration of teeth. Some of them are described below.

Obliteration of pulp chamber

Obliteration of pulp chamber may cause by trauma, especially in the formative phase. In this condition, teeth appear *darker* than normal. Maxillary incisors are commonly affected.

Erythroblastic fetalis

It is hemolytic anemia of the newborn caused due to transmission of antibody and excessive hemolysis of erythrocyte.

Erythroblastosis fetalis is based on immunization of Rh-negative mother by Rh-positive red cells of the fetus or perhaps by previous transfusion of Rh-positive blood cells. The mother produces anti-Rh agglutinin. The passage of this soluble substance into the circulation of infant causes complete destruction of the fetal erythrocytes.

Blood pigments like bilirubin and biliverdin are formed which are deposited resulting in stain. Color varies from *green, bluish green to yellow brown or gray*. This is also called as *chlorodontia*. The color of pigment is gradually reduced which is noticed particularly in the anterior teeth. It is transient situation and usually will correct itself with eruption of permanent teeth.

Neonatal hepatitis

Yellowish brown color of primary teeth caused by incorporation of bile pigment during formation of enamel and dentin.

Porphyria

It is an autosomal recessive condition. It is an inborn error in metabolism in which hepatoporphyrin circulating in blood is seen in urine, teeth and bone.

The deciduous and permanent teeth may show *red or brown or pinkish* discoloration (**Fig. 9-72**) which is called as *erythrodontia*. Under ultraviolet light, the teeth always exhibit *red fluorescence*. It occurs due to its physical affinity of calcium phosphate.

Congenital defect in bile duct

In children with this disease, the primary teeth may become discolored by bile pigment, generally *green* discoloration is seen.

Tetracycline Staining

Discoloration of either deciduous or permanent teeth may occur as a result of prophylactic or therapeutic regimen instituted for pregnant females or infants.

Mechanisms

It may cause discoloration during formation period, tetracycline react with calcium to form calcium

Fig. 9-72: Brown discoloration seen in patient of porphyria.

orthophosphate complex. The minimum amount required to produce discoloration is 21 /mg/kg/body weight. It is deposited during mineralization.

Clinical features

It also causes enamel hypoplasia which may be seen in primary as well as in permanent teeth.

It can be demonstrated as *golden fluorescence* in ultraviolet light, which is more intense in dentin than enamel. Bands are more intense toward DEJ. It shows *yellow to brown* discoloration of teeth (**Figs 9-73 and 9-74**). The location coincides with the part of tooth developing at the time of administration of tetracycline.

Fig. 9-73: Tetracycline stain.

It is usually seen with different color in different forms of tetracycline.

- *Chlortetracycline*—gray-brown
- *Oxytetracycline*—yellow
- *Demeclocycline*—yellow
- *Doxycycline*—there is no changes in teeth color.

Fig. 9-74: Yellowish discoloration of teeth due to tetracycline staining.

Congenital Heart Disease

Children with cyanotic heart disease may have maxillary incisors of *milk color* or *bluish violet color*. It may be due to mouth breathing or poorly oxygenated blood.

Oxalosis

It is an autosomal recessive condition. In this disorder, oxalate is deposited in kidney. The *slate gray intrinsic* stain has been demonstrated with odontoblasts, dentinal tubules and within dental pulp.

Discoloring Agents

- *Food and drink*—stain with beverage results in staining on the lingual side of teeth. Foods that contain more chlorophyll produce *green discoloration* of enamel.
- *Tobacco*—tobacco chewing or smoking causes *yellowish brown to black* discoloration of teeth (Fig. 9-75). Tar present

Fig. 9-75: Tobacco stain seen on the lingual surface of teeth.

in the tobacco dissolve in the saliva and penetrates the pits and fissure of enamel.

- *Restorative materials*—incorporation of amalgam in dentinal tubules results in *black to gray discoloration* stains. Deep lingual metallic restoration on anterior incisor can produce grayish discoloration on the labial surface.
- *Medicaments*—silver AgNO_3 used as caries preventing agent and cauterizing agent causes *brownish discoloration* and *black silver* particles in dentinal tubules. Iodine and iron causes *black* discoloration (Fig. 9-76). Copper and nickel can also produce *green* stain.

Fig. 9-76: Black discoloration of the teeth seen due to iron in a female patient.

- *Chromogenic bacteria*—chromogenic bacteria in the oral cavity can stain the teeth to *green, brown, black or orange color*. Bacillus group of bacteria stain the teeth by orange color. Actinomyces species stain the teeth black. Stains from chromogenic bacteria are secondary to the formation of ferric sulfide which is form due to interaction between bacterial hydrogen sulfide and iron in the saliva or gingival crevicular fluid.
- *Chlorhexidine and stannous fluoride stain*—fluoride staining is associated with the use of 8% stannous fluoride. It will produce black stain. Chlorhexidine is associated with yellowish brown stain which involve interproximal surface near the gingival margin.

Different Types of Stains according to Color

Black stain

It usually results due to contact with certain metallic elements such as silver, iron and lead.

It may appear as thin line running approximately 1 mm or so above the gingival margin, it may occur on both the facial and lingual surfaces of teeth.

Stain is firmly attached to the surface but remains extrinsic, thus it may be removed by brush and abrasives. But, it recurs later on.

Green stain

It usually occurs as thick deposit involving the cervical one-third of facial surface of maxillary incisors of young children. It affects boys more frequently than girls.

It is associated with poor oral hygiene and decalcification is sometimes present in enamel, underlying the deposit. It occurs due to chromogenic bacteria or fungi or it may be caused by bacterial action on remnants of enamel cuticle. It is extrinsic and may be removed by simple brushing and abrasive.

Orange stain

It occurs infrequently and usually involve both facial and lingual surfaces of the incisors. It is easily removed than green stain and its cause is unknown but it is believed to be the result of chromogenic bacteria. It is associated with poor oral hygiene and removed with the help of brush and abrasives.

Brown stain (Fig. 9-77)

It can be seen in non-smokers and is usually lighter brown than that of tobacco and form a tenacious, but delicate film on surface of the teeth. It is usually seen more commonly on lingual surface of lower incisors and buccal surface of maxillary molar teeth. It is formed due to altered salivary mucins which have undergone change through the action of bacterial enzymes.

Fig. 9-77: Brown staining occurs in patient due to tobacco consumption and patient is also having fluorosis.

Management**Extrinsic**

Scaling and polishing with paste containing fine powdered pumice.

Intrinsic

Fluoride stains are treated by applying bleaching solution. It consist of

- Anesthetic ether—0.2 ml
- HCl 30%—1 ml etches the enamel surface.
- H₂O₂ 30%—1 ml bleaches enamel.

Definitions

Congenital

Present at or before birth but not necessarily inherited, i.e. transmitted through the genes.

Hereditary

They are apparent at birth but some may not become evident for years.

The cell consists of cytoplasm and nucleus. Nucleus of each somatic cell contains 23 pairs of chromosome out of which one is the pair of sex chromosome; rest 22 pairs of chromosomes are called as *autosomes*. *Chromosome* is a nuclear structure composed of DNA, which contains units of hereditary gene. *Gene* is a portion of DNA coded for the synthesis of specific protein or polypeptide chain. Gene is determinants of hereditary characteristics. *Locus* is the site occupied by the gene on chromosome. An *allele* is number of alternative form that gene may take.

If both the allele at a given locus is identical to pair, it is called as *homozygous* and if the alleles are different it is called as *heterozygous*. A gene showing trait in heterozygous is considered as *dominant*. Genes are transmitted from one generation to other in a generally predictive way.

Autosomal Dominant Inheritance

- Every affected person has at least one affected parent.
- Males and females are both affected likely.
- There is no skipping of generation.
- Affected person typically transmits trait to their offsprings.

Autosomal Recessive Inheritance

- Appear only in their siblings, not on their offspring parent or other relatives.

- $\frac{1}{4}$ siblings are affected.
- Males and females are equally likely to be affected.

X-linked Dominant

- Since females have twice as many X chromosomes, they exhibit a higher frequency of trait.
- Affected female will transmit the gene to $\frac{1}{2}$ of her offsprings.

X-linked Recessive

- Incidence of the trait is much higher in males than in females.
- Affected man can transmit it to his daughters who are carriers.
- Trait cannot be transmitted from father to son.

Developmental anomalies of the head and neck are originated during transformation of branchial system into adult's derivatives. They are also result from failure of migration of neural crest cells.

Developmental Disturbances of the Jaws

Agnathia

It is also called as '*hypognathous*'. Agnathia, derived from Gnathus meaning the jaws, is total absence of either one or both the jawbones. This is very rare condition.

Clinical Features

- *Absence of mandible*—if mandible is absent, the upper part of the face may be normal and the skin of the lower part will be continuous with the suprasternal integument.

- *Hyoid bone*—the hyoid bone is sometimes absent, despite the presence of a rudimentary tongue.
- *Vertical slit*—in place of buccal orifice, there may be a vertical slit.
- *Deformed ear*—in case of unilateral absence of mandibular ramus, it is not unusual for ear to be deformed or absent.
- *Associated abnormalities*—there may be absence of ears, hypoplastic tongue, cleft palate, dysplastic ears, hypertelorism, microstomia, narrow auditory canal with palpebral fissures slanting down.

Management

- *Surgical reconstruction*—surgical reconstruction though it is difficult it should be carried out.

Micrognathia

Micrognathia is severely deficient jaw, which most commonly affects the mandible. It is common to see individuals having a very small mandible.

Types

- *Apparent micrognathia*- this is not due to abnormality of small jaw, in terms of size but rather to an abnormal positioning or abnormal relation of one jaw to another, which produces illusion of micrognathia.
- *True micrognathia*—It is due to small jaw. It is again classified as
 - Congenital
 - Acquired

Etiology

Congenital

- *Congenital abnormalities*—in many instances it is associated with other *congenital abnormalities*, particularly congenital heart disease and Pierre Robin syndrome (cleft palate, micrognathia, glossoptosis).
- *Forceps delivery trauma*—one of the main causes of this condition is the use of forceps during birth where the baby is pulled out by clamping a pair of forceps on either side of the head. If the joint in this area, called the temporomandibular joint is badly bruised, the mandible does not develop. Sometimes this condition is also associated with congenital heart disease.

Acquired

- *Ankylosis*—acquired type is post-natal type and result from disturbances in the area of *T.M joint* (ankylosis) (Fig. 10-1).
- *Mouth breathing*—mouth breathing can be a predisposing factor for maxillary micrognathia.

- *Agenesis of condyle*—agenesis of condyle also results in true mandibular micrognathia.
- *Posterior positioning*—posterior positioning of mandible with regard to skull or to a steep mandibular angle result in an apparent retrusion of the jaw.

Fig. 10-1: Acquired micrognathia occurs due to ankylosis of jaw.

Clinical Features

- *Micrognathia of maxilla*—it is due to deficiency of premaxillary area and patient with this deformity appears to have the middle third of face retracted.
- *True mandibular micrognathia*—it is uncommon and patient appears clinically to have severe retrusion of chin, steep mandibular angle and deficient chin button.
- *Signs*—micrognathia is one of the causes of abnormal alignment of teeth. This can be seen by observing the occlusion of teeth. Often, there will not be enough room for the teeth to grow. If the upper jaw is short, then, occlusion may be abnormal.
- *Symptoms*—in true micrognathia, the jaw is small enough to interfere with feeding of the infant and may require special nipples in order to feed adequately. There may be difficulty in respiration. Due to the small size of the arch, the jaw is not able to accommodate the tongue, which is forced back into the oropharynx, blocking the air passage.
- *Syndromes associated with micrognathia*—Pierre Robin syndrome, Hallerman-Streiff syndrome, trisomy 13, trisomy 18, Turner's syndrome, Treacher-Collins syndrome and Marfan's syndrome.

Management

- *Orthognathic surgery*—this is recommended treatment modality for micrognathia. This surgery is followed by orthodontic appliance to correct malocclusion.

- *Small maxilla*—if upper jaw is short, then it can be corrected with surgical orthodontic treatment by properly aligning the teeth and then moving surgically and elongating the short maxilla, in order of three to four millimeters of the upper central incisors to show when an individual is smiling.
- *Small mandible*—small mandible can be corrected, depending on the degree of deformity and problem, advancement of mandible and chin surgically.

Macrogathia

It refers to the condition of abnormally large jaws. It is also called as '*megathia*'. Macrogathia literally means a large jaw. The mandible is most often affected in this case giving rise to a condition where the bone protrudes.

Etiology

- *Pituitary gigantism*—there is generalized increase in size of entire skeleton.
- *Paget's disease of bone*—overgrowth of cranium and maxilla occurs.
- *Acromegaly*—progressive enlargement of mandible owing to hyperpituitarism in adults.

Clinical Features

- *Prognathism*—mandibular protrusion or prognathism is common occurrence, which is due to disparity in the size of maxilla to mandible and posterior positioning of maxilla in relation to the cranium.
- *Mandible*—mandible is measurably larger than normal. Increased mandibular body length.
- *Gummy smile*—in certain patients with congenital abnormalities, there may be elongation of maxilla. There is much "show" when the patient smiles, so that there is a so-called "gummy" smile. This is due to the upper jaw being too long.
- *Ramus*—large ramus which forms less steep angle with body of mandible.
- *Chin*—there is prominent chin button.

Management

- *Osteotomy*—resection of portion of mandible to decrease the length, followed by orthodontic treatment.

Facial Hemihypertrophy

It is also called as '*Friedreich's disease*', '*hemihyperplasia*'. It may involve entire half of the body, one or both limbs, face, head and associated structures. It represents the hyperplasia of the tissue rather than hypertrophy of the tissue.

Etiology

- *Endocrine dysfunction*—hormonal imbalance may lead to hemihyperplasia of the face.
- *Genetic*—incomplete twinning, chromosomal abnormalities and localized alteration of intrauterine development also lead to facial hemihypertrophy.
- *Vascular abnormalities*—lymphatic and vascular abnormalities may act as causative factors.
- *Neurogenic*—some neurogenic malformation may act as causative factors for this disease.

Terminology

- *Complex hemihyperplasia*—in this, one whole side of the body is affected.
- *Simple hemihyperplasia*—hyperplasia is limited only to one limb.
- *Hemifacial hyperplasia*—if the enlargement is confined to one side of the face.

Clinical Features

- *Age and sex distribution*—it has vague onset, usually in childhood, adolescence or early adult life. Females are affected more than males.
- *Sites*—it involves the eyelids, cheeks, lips, facial bones, tongue, ears and tonsils. It is more common on right side of body.
- *Symptoms*—occasionally, poorly localized, vague, painful sensation in muscles affected.
- *Appearance*—enlargement of one half of the head present since birth. Enlarged side grows at a rate proportional to uninvolved side (**Fig. 10-2**).
- *Associated abnormalities*—it is associated with other abnormalities like mental deficiency, skin abnormalities, compensatory scoliosis, and hemi-megalocephaly.

Fig. 10-2: Enlargement of one half of face on left side occurs in facial hemihypertrophy.

(hypertrophy of one cerebral hemisphere with ipsilateral ventricular dilatation).

- *Skin lesion*—pigmentation, hypertrichosis, telangiectases and hemangioma may occur on skin.
- *Syndrome associated*—syndromes associated with facial hemihypertrophy are Proteus syndrome and Klippel-Trenaunay-Weber syndrome.

Oral Manifestations

- *Dentition is abnormal in three respects*—crown size, and root may be large. Rate of development of permanent teeth on the affected side is more rapid and erupt before their counterparts on the uninvolved side. Primary teeth shed early.
- *Bone*—bone of maxilla or mandible is also enlarged.
- *Tongue*—tongue is commonly involved and bizarre patterns of enlargement of papilla, in addition to general unilateral enlargement of tongue.
- *Buccal mucosa*—buccal mucosa frequently appears velvety and may hang in soft pendulous folds on affected side.

Radiographic Features

- *Bone enlargement*—enlargement of bone on affected area. The malar bone, zygomatic process and temporal bone may be enlarged in all diameters, in some cases.
- *Alveolar process*—the alveolar process is enlarged in some cases on affected side (**Fig. 10-3**).
- *Mandibular canal*—it also increases on the affected side.
- *Teeth*—crown size of the tooth is enlarged.

Fig. 10-3: Enlargement of bone and teeth on the right side of patient (Courtesy Dr Datarkar).

Diagnosis

- *Clinical diagnosis*—enlargement of one side of face can be noticed clinically.
- *Radiological diagnosis*—it will also show enlargement of bone and teeth on one side.

Management

- *Cosmetic repair*—cosmetic surgery should be performed which includes soft tissue debulking, face lifts and Orthognathic surgery.

Facial Hemiatrophy

It is also called as 'Parry-Romberg syndrome', 'Romberg hemifacial atrophy', 'hemifacial microstomia' and 'progressive facial hemiatrophy'. Parry-Romberg syndrome is a rare disorder characterized by slowly progressive wasting (atrophy) of the soft tissues of half of the face (hemifacial atrophy). Wasting is associated with skin, cartilage, connective tissue, muscle and bone. It is described by Parry in 1825 and well documented by Romberg in 1846.

Etiopathogenesis

- *Idiopathic*—In most cases, Parry-Romberg syndrome appears to occur randomly for unknown reasons (sporadically).
- *Familial*—certain studies state that it has got familial occurrence.
- *Localized scleroderma*—in scleroderma there is constriction of tissue which may lead to progressive hemifacial atrophy.
- *Malfunction of sympathetic nervous system*—atrophic malfunction of cervical sympathetic nervous system can lead to neurotrophic change which in turn leads to hemiatrophy.
- *Trigeminal neuralgia*—peripheral trigeminal neuralgia is associated with hemiatrophy in some cases.
- *Loss of adipose tissue*—this will lead to shrinkage of soft tissue.

Clinical Features

- *Age*—onset noted in 1st or 2nd decades of life which are apparently normal at birth. In rare cases, the disorder is apparent at birth.
- *Location*—in most cases, progressive tissue wasting is limited to one half of the face, usually the left side.
- *Onset*—onset is marked by white line furrow or mark on one side of face or eyebrow near midline.
- *Progress*—in most affected individuals, hemifacial atrophy typically progresses over approximately three to five years and then ceases.
- *Coup de sabre*—some patients may show sharp line of demarcation resembling large linear scar between normal and abnormal skin. This is called as coup de sabre.
- *Skeletal like appearance*—affected areas may demonstrate shrinkage and atrophy of tissues beneath the skin

(subcutaneous tissue), in the layer of fat under the skin (subcutaneous fat) and in underlying cartilage, muscle and bone. If disease is not limited then patient may get skeletal-like appearance.

- **Skin**—in addition, the skin overlying the affected areas may become darkly pigmented (hyperpigmentation), in some cases, certain areas of white (depigmented) patches (vitiligo). There may be hollowing of cheek and eyes may appear depressed in the orbits.
- **Neurological manifestation**—this may include severe headache that lasts for extended periods of time and may be accompanied by visual abnormalities, nausea and vomiting (migraine). There are also facial pain due to trigeminal neuralgia. There are periods of uncontrolled electrical disturbances in brain (*seizures*) that usually are characterized by rapid spasms of a muscle group that spread to adjacent muscles (*contralateral Jacksonian epilepsy*).
- **Hair**—there is graying (blanching) of hair as well as abnormal bald patches on the scalp with loss of eyelashes and the middle (median) portion of eyebrows (alopecia).
- **Skull changes**—there is underdevelopment of the base of skull, in some cases the face is affected. When the malar bone is small, the side of the face is flat but an absent malar bone produces a depression inferior to the orbit.
- **Face**—the soft tissue of face are small and thinner than normal.
- **Ear**—aplasia or hypoplasia of external ear. The ear canal is missing.

Oral Manifestations

- **Lip and tongue**—many individuals also experience atrophy of half of the upper lip and tongue.
- **Teeth**—delayed eruption or wasting of the roots of certain teeth on the affected side. This will lead to malocclusion of teeth.
- **Deviation of jaws**—while opening the mouth, jaw is deviated on the affected side.
- **Jaws**—growth of jaws and teeth is affected. Ramus is deficient vertically and there is delay in mandibular angle development. The mandibular body can be shorter than normal.
- **Posterior open bite**—due to mandibular hypoplasia on affected side there may be unilateral posterior open bite.

Radiographic Features

- **Size reduction**—reduction in size of bone on affected side (**Fig. 10-4**). There is also reduction in size of condyle, coronoid process or overall dimension of body and ramus of mandible. The affected side of the face is smaller in all dimensions than the opposite side.

Fig. 10-4: Hemifacial atrophy presenting as reduced size of the jaw on affected side (arrow).

Diagnosis

- **Clinical diagnosis**—white line or furrow on one side and patient is having ‘coup de sabre’.
- **Radiological diagnosis**—reduction of size of bone on affected side.

Differential Diagnosis

- **Mandibulofacial dysostosis**—hereditary pattern is present and cleft palate is also seen.
- **Hemifacial microstomia**—these are congenital and non-progressive conditions.
- **Post-traumatic atrophy**—history is important.
- **Partial lipodystrophy**—it is usually bilateral.
- **Goldenhar syndrome**—it is congenital and non-progressive.

Management

- **Surgical reconstruction**—it primarily involves augmentation of the affected areas. Surgery is deferred unless diseased process is burned out.
- **Orthodontic treatment**—it is given for the correction of malocclusion.
- **Other treatment modalities**—it includes injection of silicones and bovine collagen, inorganic implants and autologous tissue transfer.

Hemi-maxillofacial Dysplasia

It is ‘*segmental odontomaxillary dysplasia*’. Etiology of this condition is unknown and many times, it is mistaken as craniofacial fibrous dysplasia or hemifacial hyperplasia. This condition remains stable.

Clinical Features

- **Age**—it is frequently encountered in younger patient.
- **Symptoms**—there is painless unilateral enlargement of the maxillary bone.
- **Gingiva**—fibrous hyperplasia of gingiva occurs in majority of patient.

- **Teeth**—maxillary premolar are missing and primary teeth in the affected area show enamel defect.
- **Becker's nevus**—some patients may be associated with hypertrichosis and hyperpigmentation (Becker's nevus).

Radiological Features

- **Trabeculae**—trabeculae are thickened and are vertically oriented resulting in granular appearance.
- **Maxillary sinus**—it is smaller in size on the affected side.

Diagnosis

- **Clinical diagnosis**—unilateral enlargement of maxillary bone with fibrous hyperplasia of gingiva will give clue to diagnosis
- **Radiological diagnosis**—sinus is smaller on radiograph.

Management

- **Orthodontic therapy**—some patients may require orthodontic therapy.
- **Orthognathic surgery**—it is rarely recommended in patient with segmental odontomaxillary dysplasia.

Cleidocranial Dysplasia

It is also called as 'cleidocranial dysostosis', 'Marie and Sainton disease', 'craniocleido-dysostosis'.

Etiology

- **Hereditary**—it appears as a true dominant Mendelian characteristic.
- **Genetic**—incomplete penetration of genetic trait. There is defect in CBFA I gene chromosome.

Clinical Features

- **Sex**—the disease affects men and women with equal frequency.
- **Sites**—it primarily affects skull, clavicle and dentition.
- **Shoulder meet in midline**—there may be complete absence of clavicle and patients have unusual mobility. They can bring their shoulders forward until they meet in midline (**Figs 10-5A and B**).
- **Head**—the head is brachycephalic (reduced anterior-posterior dimension but increased skull width) or wide and short.
- **Skull**—in skull the fontanels often remain open or at least exhibit delayed closing and for this reason, tend to be rather large. Open skull suture and multiple wormian bones are present and there is occasional stunting of long bone.
- **Lacrimal and zygomatic bone**—lacrimal and zygomatic bone are also underdeveloped.

- **Sagittal suture**—sagittal suture is characteristically sunken, giving skull flat appearance.
- **Nose**—nasal bridge is depressed with a broad base.

Figs 10-5 A and B: Patient can bring his shoulders forward so that they can meet in midline. Also note the depressed nasal bridge.

Oral Manifestations

- **Micrognathia**—maxilla and paranasal sinus are underdeveloped, resulting in maxillary micrognathia.
- **Maxilla**—maxilla is underdeveloped and is smaller than normal, in relation to mandible.
- **Prognathism**—maxilla is small and mandible is usually normal in size, which gives the appearance of prognathism.
- **Teeth**—prolonged retention of primary dentition and delayed eruption of permanent dentition. Numerous unerupted teeth are found which are most prevalent in the mandibular, premolar and incisor area (**Fig. 10-6**).
- **Palate**—high narrow arched palate and cleft palate may be common.
- **Hypoplasia of enamel**—the crown may be pitted as a result of enamel hypoplasia.

Fig. 10-6: Numerous unerupted teeth seen in patient with cleidocranial dysplasia.

Radiographic Features

- *Skull finding*—skull film reveals open sutures (**Fig. 10-7**), presence of wormian bones, widened cranium, delayed ossification of fontanelles, frontal and occipital bossing and basilar invagination.

Fig. 10-7: Open suture seen in cleidocranial dysplasia patient.

- *Chest examination*—examination of chest reveals malformation and absence of clavicles (**Fig. 10-8**).

Fig. 10-8: Absence of clavicle seen on chest examination in cleidocranial dysplasia.

- *Teeth*—jaw examination reveals prolonged retention of primary dentition. The unerupted teeth are frequently displaced to occupy an oblique or horizontal position in the jaw.
- *Supernumerary teeth*—presence of supernumerary teeth usually in anterior region (**Fig. 10-9**). The supernumerary teeth in this area often show anomalous and distorted roots.
- *Jaws*—there is small underdeveloped jaw. There is also flattened mandibular angle (**Fig. 10-10**) and overgrowth

Fig. 10-9: Multiple supernumerary teeth found in cleidocranial dysplasia.

of cranial base; anteroposteriorly. Pointed coronoid process.

- *Roots*—roots of teeth are often some what short and thinner than the normal.

Fig. 10-10: Flattened mandibular angle seen in cleidocranial dysplasia.

Diagnosis

- *Clinical diagnosis*—meeting shoulder in the midline is typical feature of cleidocranial dysostosis.
- *Radiological diagnosis*—supernumerary teeth, open sutures and absence of clavicle are present in cleidocranial dysostosis.

Management

- *Management of skull and clavicle anomalies*—there is no treatment require for this anomalies. Patient can live its normal life.

- **Dental care**—as patient may be having supernumerary teeth, they should be extracted. Prosthetic replacement of teeth should be carried out. Unerupted teeth should be extruded orthodontically.

Craniofacial Dysostosis

It is also called as '*Crouzon's disease or syndrome*'. In some instances, Crouzon syndrome is inherited as an autosomal dominant trait. In other cases, affected individuals have no family history of disease. The disorder is characterized by distinctive malformations of the skull and facial (craniofacial) region.

Clinical Features

- **Age**—Crouzon's syndrome is a rare genetic disorder that may be evident at birth (congenital) or during infancy.
- **Craniosynostosis**—in most infants with Crouzon syndrome, the fibrous joints between certain bones of the skull (cranial sutures) close prematurely (craniosynostosis).
- **Proptosis**—in addition, facial abnormalities typically include unusual bulging or protrusion of the eyeballs (proptosis) due to shallow eye cavities (**Fig. 10-11**)
- **Strabismus**—outward deviation of one of the eyes (divergent strabismus or exotropia); widely spaced eyes (ocular hypertelorism). This may lead to blindness of the patient.
- **Cranial malformation**—the premature closing of suture may result in brachycephaly (short head), scaphocephaly (boat shaped head), or trigonocephaly (triangle shaped head). In extreme cases patient may demonstrate '*clover leaf skull*' (kleeblatt schadel deformity).

Fig. 10-11: Ocular proptosis with triangular frontal defect seen in patient of Crouzon's syndrome.

- **Frontal bone**—bulging of frontal bone in midline, over the nose and downward sloping of back of head. There is protuberant frontal region with an anterior-posterior ridge overhanging the frontal eminence and often passing to the root of nose (triangular frontal defect).

Oral Manifestations

- **Maxillary hypoplasia**—maxillary hypoplasia with shortened anteroposterior dimensions of maxillary arch.
- **Parrot beak**—in some cases, facial angle is exaggerated and the patient nose is prominent and pointed, resembling 'parrot beak' (**Fig. 10-12**)

Fig. 10-12: Parrot beak appearance of the patient seen in Crouzon's syndrome. There is also midfacial hypoplasia.

- **High arched palate**—dental arch width is reduced and this gives an appearance of high arch palate (**Fig. 10-13**).

Fig. 10-13: High arch palate seen in Crouzon's syndrome.

- **Teeth**—unilateral or bilateral cross-bite is evident with open bite and crowding in mandibular teeth. Shovel shaped maxillary incisors cleft lip and palate are also evident (**Fig. 10-14**)

- *Sinus*—the antrum are small and underdeveloped. The mandible is large as compared to maxilla, so there is prognathism.

Fig. 10-14: Unilateral cross-bite on left side in Crouzon's syndrome.

Radiographic Features

- *Absence of sutures*—digital marking in skull as a result of increased intracranial pressure from early synostosis of cranial sutures.
- *Beaten silver appearance*—the cranial walls are thin with multiple radiolucencies appearing as depressions or scalloped appearance of beaten silver (Fig. 10-15).
- *Others*—malformation of calvarium, flattened mandibular angle, conical teeth and partial anodontia.

Fig. 10-15: Beaten silver appearance seen in Crouzon's syndrome.

Diagnosis

- *Clinical diagnosis*—high arch palate, with midface deformity, proptosis is a typical feature of Crouzon syndrome.
- *Radiological diagnosis*—beaten silver appearance seen in Crouzon syndrome.

Management

- *Midfacial advancement*—this is done to correct midfacial hypoplasia.
- *Craniectomy*—it is needed to alleviate the raised intracranial pressure.
- *Fronto-orbital advancement*—this is done to correct ocular defect.

Mandibulofacial Dysostosis

It is also called as 'Treacher Collins syndrome' and 'Franceschetti syndrome'. It is often inherited as autosomal dominant trait. It is derived from first and second branchial arch. It results from failure or incomplete migration of neural crest cells to the facial region.

Clinical Features

- *Zygomatic bone*—underdevelopment of zygomatic bone, resulting in midfacial deformities.
- *Eyes*—there is downward inclination of palpebral fissure. There is deficiency of eyelashes. In some cases, eyes assume corresponding slant. A notching (*coloboma*) from the outer third of lower eyelids, There is varying degree of visual impairment in some cases.
- *Ears*—affected infants may also have underdeveloped (hypoplastic) and/or malformed (dysplastic) ears (Fig. 10-16) (pinnae) with blind ending or absent external ear canals (microtia), resulting in hearing impairment (conductive hearing loss). Absence of external auditory canal resulting in partial or complete deafness is also found.

Fig. 10-16: Treacher Collins syndrome showing malformed ear.

- *Malar bones*—the normal prominence of cheek is either missing or reduced depending upon the presence or absence of malar bone. There is usually hypoplasia of malar bone.
- *Neurological disorders*—secondary mental deficiency.
- *Fistulae*—blind fistulae between the angle of ears and the angle of mouth.
- *Associated features*—anal atresia/stenosis, congenital cardiac anomaly, rectovaginal fistula and tracheo-esophageal fistula.

Oral Manifestations

- *Appearance*—underdevelopment of mandible with steep mandibular angle. Due to this, lower anterior teeth stand away from upper teeth, when the mouth is closed.
- *Fish or bird appearance*—facial appearance sometimes resembles fish or bird (**Fig. 10-17**).
- *Micrognathia*—an incompletely developed, abnormally small lower jaw.
- *Macrostomia*—an unusually large mouth.
- *Palate*—there is presence of high arch palate with cleft palate.
- *Malocclusion*—abnormal position and malocclusion of teeth with anterior open bite.

Fig. 10-17: Fish face appearance seen in Treacher Collins syndrome.

Radiographic Features

- *Zygomatic bone*—reduction in size of zygomatic bone.
- *Maxillary sinus*—maxillary sinus is underdeveloped or completely absent (**Fig. 10-18**).
- *Articular eminence*—articular eminence is either shallow or absent.

Fig. 10-18: Underdeveloped maxillary sinus seen in cases of Treacher Collins syndrome.

- *Mastoid air cells*—mastoid air cells are reduced or absent.
- *Jaws*—hypoplasia of mandible and maxilla showing accentuation of antegonial notch and steep mandibular angle, which gives impression that the mandible is bending in an inferior and posterior direction (**Fig. 10-19**).
- *Teeth*—partial anodontia and malformation of teeth.

Fig. 10-19: Mandible is bending in inferior direction in cases of Treacher Collins syndrome.

Management

- *Cosmetic surgery*—improvement and surgical interventions should be done to improve osseous and ear defect.

Hyperplasia of Maxillary Tuberosity

There is bilateral enlargement of maxillary tuberosity. It is usually seen in adults. There is difficulty in wearing denture and normal mastication. Radiologically, bone is

more opaque than normal. Surgical removal of maxillary tuberosity can be done.

Hyperplasia of Coronoid Process

It is seen in adults, with onset at puberty. There is limited opening, which may be unilateral or bilateral. Enlargement can be seen radiologically. Surgical removal can be done.

Focal Osteoporotic Bone Marrow Defect

It is area of hematopoietic marrow which is large in size to confuse with intraosseous radiolucency.

Etiopathogenesis

- *Persistence of fetal marrow*—they are derived from bone marrow hyperplasia of persisting embryonic marrow remnants.
- *After tooth extraction*—there may be aberrant bone regeneration after tooth extraction.
- *Increased demand for erythrocyte*—marrow hyperplasia can occur in response of increased demand for erythrocyte.
- *Other factors*—it can also occur in trauma and local inflammation.

Clinical Features

- *Sex*—it is more common in females than males.
- *Common sites*—molar, premolar region in mandible.
- *Symptoms*—asymptomatic with history of pain in that region.

Radiographic Features

- *Location*—it is most common in edentulous areas.
- *Internal structure*—radiolucent area demonstrates internal trabeculation. Occasionally, trabeculae with spotty radiopaque flecks are seen within the radiolucency (Fig. 10-20).

Fig. 10-20: Focal osteoporotic bone marrow defect showing radiolucent defect with spotty radiopaque flecks.

- *Margins*—margins may be well-defined or less defined. They may be corticated or non-corticated.

Diagnosis

Diagnosis is made by exclusion.

Differential Diagnosis

- *Residual dental infection*—sign of infection is present.
- *Central neoplasm*—margins are not so corticated.

Management

There is no specific treatment for it.

Chondroectodermal Dysplasia

It is also called as 'Ellis-van Creveld disease'. The Ellis-van Creveld (EvC) syndrome was first described by Dr. Richard W.B. Ellis of Edinburgh and Simon van Creveld of Amsterdam.

It is congenital and the patient present evidence of chondrodysplasia, ectodermal dysplasia, polydactylism and congenital morbus cordis.

Clinical Features

- *Hands*—post-axial polydactyly in the hands, i.e. an extra finger lateral to the normal fifth finger, is a consistent finding. Polydactyl in the feet is a rare finding.
- *Bone dysplasia*—bone dysplasia is characterized by acromesomelia, i.e. relative shortening of the distal (acromelic) and middle (mesomelic) segments. It may interfere with the ability to make a tight fist.
- *Knees*—there may be a deformity of the knees that, frequently progress and causes a significant malalignment.
- *Nails*—the nails of the fingers and toes are dysplastic.
- *Congenital heart defect*—congenital heart defects may include hypoplasia of aorta, atrial and ventricular septal defects and a single atrium. There is dwarfism, i.e. the long bones being short and the trunk of normal length.
- *Hair*—there is absence of nails and the hair tend to be fine and sparse.

Oral Manifestations

- *Teeth*—teeth are deficient in number; and those which develop are small, rudimentary, conical, spaced and irregular in position. The teeth are affected, with eruption occurring at birth or shortly thereafter.
- *Deciduous molars*—the deciduous molars present a crenate occlusal surface. The permanent dentition is more likely to be defective than the deciduous one. Eruption is delayed.

- **Partial hairlip**—the lip deformity often referred to as a “partial hairlip” results from an abnormally short upper lip, which may also be sunken secondary to hypoplasia of maxilla.

Radiographic Features

As mentioned previously, these are shorter distal and middle phalangeal segments, in relation to the proximal phalangeal segments. Deciduous molars show typical shape.

Diagnosis

- **Clinical diagnosis**—polydactyly with hairlip and partial anodontia will favor the diagnosis of Ellis-van Creveld syndrome.

Management

- **Surgical**—management of hairlip is done by surgical method for cosmetic reason.

Arhinencephaly

It is a developmental abnormality of the skull and face in which there is absence or deficiency of the olfactory portion of brain.

Clinical Features

- **Hypotelorism**—absence of the vertical and cribriform plates of ethmoid and of crista galli result in the orbits being more closely set, a condition known as *hypotelorism*.
- **Lack of nasal bone**—there is depression of nose and absence of the bridge because of lack of nasal bones and nasal septum.
- **Prow of boat appearance**—in some cases, an associated deformity of the frontal portion of skull presents an angular appearance resembling ‘the prow of a boat’ presumably due to premature fusion of metopic sutures.

Oral Manifestation

- **Cleft lip**—there is wide cleft in the central portion of the lip, where the philtrum is absent and with failure of development of any part of the premaxilla, the cleft is continuous through the palate.

Diagnosis

- **Clinical diagnosis**—Hypotelorism with cleft lip and depressed nasal bridge will aid in diagnosis.

Management

- **Surgery**—surgery of cleft lip is done for cosmetic reasons and for functional reasons.

Phlebectasia

It is first used by Gerwig in 1928. It is an isolated, abnormal, fusiform or saccular dilatation of veins. It is also known as *venous congenital cyst*, *venous aneurysm*, *venous ectasia* or *essential venous dilatation*.

Etiology

- Mechanical compression of left innominate vein by a high tortuous aorta in hypertension or of venous structures between the sternum and the left innominate artery in pectus excavatum.

Clinical Features

- **Appearance**—it usually appears as isolated swelling. Swelling is not visible before the compression but as soon as patient clinch the jaws, swelling is visible (**Figs 10-21A and B**).

Fig. 10-21A: Without compression of neck no swelling is visible.

Fig. 10-21B: Note the swelling seen on left side of face below the ear after the compression (Courtesy Dr Abhishek Soni, Lecturer, Periodontia, VSPM Dental College and Research Center, Nagpur, India).

- *Age and sex distribution*—it is mostly seen in children/young adults on left side. Male: Female ratio is 2:1
- *Site*—commonly affects internal jugular vein, external jugular vein, anterior jugular vein and superficial communications.
- *Other features*—rarely arteriovenous fistulas or cardiac anomaly may be present.

Radiological Features

- *Ultrasonography*—dilated blood vessels are usually seen on ultrasonography (Fig. 10-22).

Fig. 10-22: Decompression image on sonography of phlebectasia (Courtesy Dr Abhishek Soni, Lecturer, Periodontia, VSPM Dental College and Research Center, Nagpur, India).

- *Contrast computed tomography scan*—soft tissue mass is usually seen on the CT scan. There are chances of Phleboliths formation, which can be seen in contrast CT as radiopacities (Fig. 10-23).
- *Venography*—dilated venous channels seen on venography (Fig. 10-24).

Treatment

It can be surgical, embolization or injection of sclerosing agents.

Ectodermal Dysplasia

It represents a group of inherited diseases in which two or more ectodermally derived structure does not develop. It can be autosomal dominant, autosomal recessive and

Fig. 10-23: Contrast CT picture (Courtesy Dr Abhishek Soni, Lecturer, Periodontia, VSPM Dental College and Research Center, Nagpur, India).

Fig. 10-24: Venography picture of jugular vein, venous dilatation (green arrow) and left jugular vein (red arrow) (Courtesy Dr Abhishek Soni, Lecturer, Periodontia, VSPM Dental College and Research Center, Nagpur, India).

X-linked. There are many types of ectodermal dysplasia but they are very rare. The most commonly occur ectodermal dysplasia is called as 'hereditary hypohidrotic (anhidrotic) ectodermal dysplasia'. This shows X-linked inheritance.

Clinical Features

- *Sex*—males are affected more frequently than females.
- *Appearance*—it is characterized by hypotrichosis, hypohydrosis and anhidrosis with saddle nose appearance.
- *Hairs*—the hair of scalp and eyebrows tend to be fine, scanty and blond.

- *Frontal bosses*—supraorbital and frontal bosses are pronounced.
- *Heat intolerance*—skin is often dry, soft, smooth and scaly with partial or complete absence of sweat glands. Such patient cannot perspire and they usually suffer from hyperpyrexia and inability to endure warm temperature (Fig. 10-25).
- *Sibling appearance*—facial appearance of these individual resemble to each other, enough to be mistaken for siblings.
- *Palate*—the palatal arch is frequently high and cleft palate may be present.
- *Salivary gland*—along with all this, since the salivary gland, including the intraoral accessory gland, are sometimes hypoplastic, they result in xerostomia and dry cracked lips with fissuring at the corners of mouth.
- *Midfacial hypoplasia*—midfacial hypoplasia results in protuberant lip of the patient. This occurs due to reduction in vertical dimension.

Fig. 10-25: Dry skin appearance of skin in patient with ectodermal dysplasia with protuberant lip.

Oral Manifestations

- *Oligodontia or anodontia*—patients with this abnormality invariably manifest oligodontia or partial absence of teeth (Fig. 10-26) with frequent malformation of any present tooth in deciduous and permanent dentition. Where some teeth are present they are commonly truncated or cone shaped.

Fig. 10-26: Absence of teeth in patient with ectodermal dysplasia.

Fig. 10-27: Reduction in vertical dimensions of alveolar bone of mandible in case of ectodermal dysplasia.

Radiological Features

- *Alveolar bone*—since the alveolar process does not develop in the absence of teeth, they appear as thin and less vertical dimension (Fig. 10-27).
- *Teeth*—radiograph will also show absence of teeth (Fig. 10-28).

Fig. 10-28: Lateral view of patient showing thin alveolar bone and absence of teeth (Courtesy Dr Chole).

Diagnosis

- *Clinical diagnosis*—absence of teeth with dry skin is valuable aid in the diagnosis of ectodermal dysplasia.
- *Radiological diagnosis*—reduction in the height of alveolar bone.
- *Special impression of fingertip*—this is taken in the childhood. This impression is taken to count density of sweat gland.

Management

- *Prosthetic replacement*—from dental point of view, partial and complete dentures should be constructed for both functional and cosmetic purpose.
- *Endogenous dental implant*—it can be considered by selecting proper site in the patient older than 5 years of age.

Gardner's Syndrome

It is also called as familial multiple polyposis. It is hereditary condition. The responsible gene for this syndrome is chromosome 5.

Clinical and Radiological Features

- *Age*—it is usually noticed in second decade of life with male predilection.
- *Colonic polyps*—these are commonly found in intestine. This polyp has high degree of transformation into adenocarcinoma.
- *Osteoma*—osteoma are most common in frontal bone, mandible, maxilla and sphenoid bone (Fig. 10-29). Osteoma in mandible is present in area of mandibular angle.
- *Facial deformity*—facial deformity may occur due presence of osteoma in the mandible.

Fig. 10-29: Osteoma seen on back of patient (Courtesy Dr Datarkar, Asso. Professor, Department of Oral Surgery, SPDC, Wardha, India).

- *Limitation of opening*—in some cases of large osteoma of mandibular angle, opening of the patient mouth may be reduced.
- *Other features*—some of the patient may have epidermoid cyst, thyroid carcinoma and desmoid tumor.

Radiological Features

- *Supernumerary teeth*—there is presence of unerupted supernumerary teeth in the jaws (Fig. 10-30).
- *Osteomas of mandible*—these areas appears to be increased in radiodensity. Size varies from small to large.

Fig. 10-30: Multiple supernumerary teeth seen in case of Gardner's syndrome (Courtesy Dr Datarkar, Asso. Professor, Department of Oral Surgery, SPDC, Wardha, India).

Diagnosis

- *Clinical and radiological diagnosis*—supernumerary teeth with osteoma in the jaw or other part of the body will favor the diagnosis of Gardner's syndrome.

Management

- *Prophylactic colectomy*—it should be done as there are high degree of transformation into malignancy.
- *Removal of jaw osteoma*—it can be removed for cosmetic reason.

Turner's Syndrome

It is also called as XO syndrome. Turner syndrome is a chromosomal condition that alters development in females. Turner's syndrome is a chromosomal condition related to the X chromosome.

Clinical Features

- *Short stature*—women with this condition tend to be shorter than average. They often have normal height for the first three years of life, but then have a slow growth rate. At puberty, they do not have the usual growth spurt (Fig. 10-31).
- *Webbed neck*—extra skin present on the neck.
- *Lymphedema*—there is also puffiness or swelling (lymphedema) of the hands and feet.

- *Other features*—there is also skeletal abnormalities, heart defects and kidney problems. Women are unable to conceive a child (infertile) because of an absence of ovarian function.
- *Middle ear infection*—in early childhood, girls who have Turner syndrome may have frequent middle ear infections. Recurrent infections can lead to hearing loss in some cases.
- *Osteoporosis*—it can develop due to lack of estrogen.

Fig. 10-31: Short stature of individual seen in Turner syndrome.

Oral Manifestation

- *Palate*—patient noticed high arch palate (**Fig. 10-32**)
- *Teeth*—eruption of teeth occurs prematurely.
- *Corner of mouth*—corners of mouth appears pulled down (**Fig. 10-33**).

Diagnosis

- *Clinical diagnosis*—webbed neck, a broad chest and short stature. Orally high arch palate with corner of mouth pull down is typical feature.

Management

- *Growth hormone injection*—growth hormone injections are beneficial in some individuals with Turner syndrome. Estrogen replacement therapy is usually started at the time of normal puberty.

Fig. 10-32: High arch palate seen in Turner's syndrome.

Fig. 10-33: Corner of mouth appear pull down in Turner's syndrome.

Kallman Syndrome

Kallman syndrome is a rare X-linked recessive disease characterized by anosmia, underdeveloped genitalia and sterile gonads.

Clinical Features

- *Sex predilection*—it affects primarily males.
- *Anosmia*—reduced or complete absence of the sense of smell. Impaired or lack of sense of smell is caused by the absence of the olfactory bulbs.
- *Underdeveloped genital*—it is apparent when they fail to begin puberty and to develop secondary sexual characteristics (**Fig. 10-34**). Kallman syndrome also affects the hypothalamus. The hypothalamus produces reduced levels of GnRH, the hormone responsible for the secretion of the hormone LH. LH is the hormone that stimulates gonadal and genital development.
- *Osteoporosis*—it can occur in some cases.

Fig. 10-34: Underdeveloped genital seen in Kallman syndrome (Courtesy Dr Rajanikant).

Oral Manifestation

- *Tooth agenesis*—it occurs more frequently.
- *Mandibular inclination*—increased mandibular inclination and mandibular angulation is also present.
- *Cleft lip*—cleft lip is also present in this syndrome. When clefting occurred, extreme retrognathism of both maxilla and mandible was seen, a deviation which worsened during growth (**Fig. 10-35**).

Fig. 10-35: Cleft lip in patient with Kallman syndrome (Courtesy Dr Rajanikant).

Management

- *Hormonal therapy*—hormone, estrogen or testosterone, replacement, and pulsatile GnRH injections should be given.

Keratotic and Non-keratotic Lesions

3

Introduction

White lesion of oral mucosa comprises of a group of conditions which can appear in variety of clinical forms. A white lesion is described as abnormal area of the oral mucosa that appear whiter than the surrounding tissue and are usually slightly raised, roughened, or otherwise of a different texture from adjacent normal tissue. The white lesion may be smooth, folded, shaggy, elevated, lacy or annular. Each of these may be in turn fissured, ulcerated, eroded or inflamed and occur as solitary, multiple, focal or diffuse lesions.

Classification of lesion is described in Table 11-1.

Normal Variation

Leukoedema

It is an abnormality of the buccal mucosa, which clinically resembles early leukoplakia.

Etiology

- *Racial*—as it is prevalent in black racial cause can be present.
- *Tobacco*—it is seen more commonly in smokers than non-smokers.
- *Poor oral hygiene*—this can also predispose for the occurrence of leukoedema.

Clinical Features

- *Age, race and sex distribution*—it is common in age group of 15 to 35 year with prevalence in black. Male predilection is in the ratio of 2:1.
- *Sites*—the most common sites of involvement are buccal mucosa and lip. The lesion is bilateral in occurrence.
- *Velvet-like folded appearance*—buccal mucosa retains the normal softness and flexibility but exhibits grayish white,

Table 11-1: Classification of lesion

Normal variation

- Leukoedema
- Fordyce's granules
- Linea alba

Non-keratotic white lesions

- Habitual cheek biting
- Burns
- Uremic stomatitis
- Radiation mucositis

Candidiasis

- Thrush
- Acute atrophic candidiasis
- Chronic atrophic candidiasis
- Id reaction
- Extraoral candidiasis
- Chronic mucocutaneous candidiasis
- Systemic candidiasis

Keratotic white lesion

- Traumatic keratosis
- Keratosis associate with dental restoration
- Intraoral skin graft
- Focal epithelial hyperplasia
- Psoriasis

Oral genodermatoses

- White sponge nevus
- Hereditary benign intra-epithelial dyskeratosis
- Pachyonychia congenita
- Porokeratosis
- Keratosis follicularis
- Warty dyskeratoma
- Hyalinosis cutis et mucosa oris
- Pseudoanthoma elasticum

slightly folded opalescent appearance that is described as epithelium covered with diffuse edematous film or *velvet-like veil* (Fig. 11-1).

- *Mother of pearl appearance*—in some cases, lesion is diffuse and shows a filmy, mother of pearl appearance, often with delicate overlapping curtain-like mucosal folds.
- *Signs*—in this disease desquamation may occur which may leave surface of the lesion eroded.

- *Diagnostic test*—it can be eliminated by the stretching and scraping of mucosa but re-establishes itself almost immediately.
- *Histological*—it shows characteristic edematous cells.

Fig. 11-1: Leukoedema showing slightly folded appearance.

Diagnosis

- *Clinical diagnosis*—faint milky folded appearance which is eliminated by stretching the mucosa.

Differential Diagnosis

- *Leukoplakia*—leukoedema has faint milky appearance, folded and wrinkled pattern as compared to definite whiteness of leukoplakia. Leukoplakia cannot be eliminated by stretching.
- *Cheek biting lesion*—it is usually unilateral in appearance as compared to bilateral occurrence of leukoedema. Tissue tag is usually seen.
- *White sponge nevus*—white sponge nevus is thicker, plaque-like. It is not eliminated on stretching.
- *Hereditary benign intraepithelial dyskeratosis*—same as white sponge nevus. It has typical microscopic features.

Management

- No treatment is necessary as it has no pre-malignant potential.

Fordyce's Granules

Fordyce's granule is a developmental anomaly characterized by heterotrophic collection of sebaceous glands at various sites in oral cavity which is covered with intact mucosa. These are usually submucosal.

Pathogenesis

It has been postulated that the occurrence of sebaceous glands in the mouth may result from the *inclusion* in the oral cavity of the ectoderm having some of the potentialities of the *skin* in the course of development of the maxillary and mandibular processes during embryonic life.

Clinical Features

- *Age and sex distribution*—it is seen in any age group with somewhat more prevalent in males as compared to females.
- *Sites*—it is most commonly found bilaterally in symmetrical pattern on mucosa of the cheek, opposite to the molar teeth (Fig. 11-2). It is also found on inner surface of lips, in retromolar area lateral to anterior faucial pillar and occasionally on the tongue, gingiva, frenum and palate.
- *Symptoms*—patient usually feels roughness to hands.
- *Appearance*—they appear as small yellow spots, either discretely separated or forming relatively large plaques often projecting slightly above the surface of tissue.
- *Surface*—they are sharply delineated with smooth surface which is not ulcerated.
- *Consistency*—they have slightly cheesy consistency.
- *Plaque-like lesion*—the granules may be isolated or they may occur in confluent sheets. Sometimes they may occur in clusters and may form plaque-like lesions.
- *Tongue*—it appears as dome-shaped nodules from a few millimeters to 2 cm in diameter on the midline dorsum of the tongue.
- *Hormonal effect*—it increases rapidly in number at puberty and continues to increase throughout the adult life.
- *Histopathological*—it consists of sebaceous acini.

Fig. 11-2: Fordyce's granules seen on buccal mucosa of patient.

Diagnosis

- *Clinical diagnosis*—small yellow discrete spot separated from oral mucosa.

Management

- As such no treatment is required but if it causes disfigurement then surgical removal can be done.

Linea Alba

It is also called as '*white line*'. Linea alba refers to the line of keratinization, found on the buccal mucosa parallel to the line of occlusion expanding to a triangular area inside each labial commissures.

Etiology

- *Dietary variation*—linea alba may occur due to variation in dietary practice. The person who is taking hard diet has got more chances of having linea alba.
- *Frictional irritation*—it may occur due to contact of teeth with buccal mucosa.
- *Increases overjet*—linea alba is more prominent in people with little overjet of molars and premolars.
- *Other factors*—some other causative agents like smoking, and environmental irritants can also lead to linea alba.

Clinical Features

- *Sites*—common sites are buccal mucosa at the line of occlusion and where the mucosa overlies the bone as in hard palate and gingiva.
- *Appearance*—palate and gingiva appears whiter than the adjacent mucosa of the soft palate and alveolar gingiva.
- *Extent of line*—line extending horizontally from commissure to most posterior teeth (**Fig. 11-3**).

Fig. 11-3: Increased line of keratinization seen in buccal mucosa at the occlusal plane.

Diagnosis

- *Clinical diagnosis*—diagnosis can be made on clinical basis by observing line at the level of occlusion.

Management

- *Spontaneous regression*—in some cases spontaneous regression can occur. As this condition is asymptomatic and does not cause any esthetics or functional problems to patient no treatment is required.

Non-keratotic White Lesions

Chronic Cheek or Lip Biting

Superficial lesions produced by frequent and repeated rubbing, sucking or chewing movements that abrade the surface of a wide area of lip or cheek mucosa without producing discrete ulceration. It is also called as '*morsicatio buccarum* (*Morsicatio means morus or bite and buccarum—buccal mucosa*)'. The lesion if present on labial mucosa then it is called as '*morsicatio labiorum* and if it is on lateral border of tongue it is called as '*morsicatio linguarum*'.

Etiology

- *Neurological*—unconscious nervous habits, uncontrolled tongue thrusting and neuromuscular disorders such as tardive dyskinesia may lead to chronic biting of cheek or lip mucosa.
- *Psychological*—stress and anxiety may lead to cheek biting. Patient is aware of the habit but refuses to accept it.
- *Dental*—occlusal discrepancies, rough tooth surface may lead to chronic trauma in cheek mucosa.

Clinical Features

- *Age and sex*—it can occur at any age with women involving more commonly than the males.
- *Site*—it usually occurs on the buccal mucosa at the level of occlusion. It can also occur on lip and lateral border of tongue.
- *Appearance*—usually there is opaque white appearance which is homogenous. In some cases, there is lacerated and reddened area usually with patch of partly detached surface epithelium (**Fig. 11-4**).
- *Margins*—it may have sharply delineated borders or in some cases it may be poorly outlined. In some cases, contused margins present with transient whitish tags of necrotic tissue around the ulcer (**Fig. 11-5**).
- *Signs*—it is rough on palpation as area becomes thickened, and scarred.

Fig. 11-4: Habitual cheek biting showing patch of partly detached epithelial surface in retromolar area.

Fig. 11-5: Contused margin present with whitish tag of necrotic tissue in habitual cheek biting.

Diagnosis

- *Clinical diagnosis*—typical clinical appearance with typical location will lead to easy clinical diagnosis of the lesion.

Differential Diagnosis

- *White sponge nevus*—in cheek biting if the cause is removed the white lesion will disappear.
- *Chemical burns*—history will confirm the diagnosis of chemical burns.
- *Reaction to locally applied medicine*—history will confirm the diagnosis.

- *Candidiasis*—it is more common on tongue and white patches can be rub off.

Management

- *Psychotherapy*—small doses of diazepam 5 to 10 mg at bed time for the management of neurological disorders. But this does not give any long-term effect.
- *Acrylic guard*—this should be given to cover the facial surface of teeth and thereby restricting access to buccal and labial mucosa.

Burns

Burns cause transient non-keratotic white appearance of the mucosa which is attributed to superficial pseudo-membrane composed of coagulated tissue with an inflammatory exudate (saliva protects oral mucosa).

Types of Burns

According to severity

- *Mild burns*—mild burn causes keratotic white lesions.
- *Intermediate burns*—intermediate burns cause localized mucositis.
- *Severe burns*—severe burns coagulate the surface of the tissue and produces diffuse white lesions. If coagulation is severe, tissue cannot be scraped off easily leaving raw and bleeding painful surface.

According to cause

- *Thermal burn*—it is caused by hot food and beverages. It may occur by snow or dry ice.
- *Electrical burn*—it is caused by electrical rods.
 - *Contact burn*—it occurs when the patient is grounded and the body act as conductor with current passing through him along the path of least resistance. These burns are fatal.
 - *Arc burn*—it is sustained when arcs or sparks appear in the gap between a live wire and tissue.
- *Chemical burns*—it is caused by chemical agents.
- *Radiation burn*—this occurs in patient under radiation therapy for the management of malignancy in the oral cavity.

Thermal Burns

Clinical features

- *Sites*—anterior 1/3rd of tongue and palate.
- *Symptoms*—there is pain which lasts for short duration.
- *Appearance*—it may produce coagulation necrosis of superficial tissue that appears whitish.
- *Signs*—in some cases, there may be frank ulceration and stripping of mucosa. Red area is tender to painful, it may blanch on pressure and there is bleeding on manipulation. Surface layer of epithelium is desquamated.

- *Pizza burns*—central palatal burns, whitish gray or ulcerated lesions on the middle third of the hard palate (**Fig. 11-6**). These also present superficial necrosis and ulceration due to combination of heat of the cheese and its adhesion to blister epithelium.

Fig. 11-6: Pizza burns showing grayish lesion of hard palate.

- *Frost bite of lip or popsicle panniculitis*—it occurs due to dry ice (snow). In this, tongue and lip are most commonly affected. It occurs due to prolonged contact of ice cream and other frozen confectionaries or very cold metal, glass object, with child's lip. There is persistent swelling and redness. Epithelium becomes dry and rough than surrounding tissues.

Management

- *Pain control*—pain can be managed by systemic analgesics and topical hydrocarbon in emollient base.
- *Infection control*—there are chances that secondary infection may occur in this patient. So to prevent secondary infection antibiotics should be given.

Electrical Burns

More commonly type of burn occurs in oral cavity in which saliva acts as conducting medium. This burn can generate 3000 degree Celsius heat and causes lot of tissue destruction.

Clinical features

- *Age*—it is usually seen in children as they can accidentally chew live wire or end of an extension cord.
- *Site*—it occurs more frequently at the commissure region of the lips.
- *Symptoms*—as there is destruction of neural tissue the lesions are usually painless. There is also loss of sensory and motor function of surrounding tissues.
- *Appearance*—the clinical appearance of the burn is a gray white tissue surrounded by narrow rim of erythema.

- *Margins*—the center of the lesion may be depressed and margins are raised.
- *Signs*—tissue begins to swell within the few hours of injury, the margin of wound become irregular and the lips protrude and control of saliva is diminished. The resulting burn of the lips and sometimes of the gingiva and tongue cause destruction and necrosis of a considerable amount of tissue. Necrotic tissues slough between 2 to 4 weeks after the accident. Following sloughing, irregular ulceration can occur.
- *Tooth germ*—developing tooth germs or buds are often destroyed in the accident with permanent cosmetic disfigurement.
- *Facial asymmetry*—when surgery is not performed the opposing lips may adhere to each other with concomitant contraction and scarring and finally asymmetrical facial appearance may result.

Management

- *Surgery*—when severe tissue damage is there, surgery is recommended. If surgery is performed after healing, multiple surgical operations are required.
- *Tetanus immunization*—this should be given to prevent tetanus.
- *Antibiotics*—this should be given to prevent secondary infection. Most commonly antibiotics given are penicillin.
- *Intraoral splints*—in order to reduce the number of surgical operations and to improve oral asymmetry, removable and fixed intraoral splints have been recommended. The appliance has two ovoid acrylic posts that extend from the mouth and flare laterally. The post is extended to maintain the commissure distance equal from the midline.

Chemical Burns

Burns due to caustic chemical agents will produce coagulation necrosis of the epithelium with subsequent inflammation. It can occur in children which hold drug in oral cavity for extended period of time.

Causes

- *Aspirin and aspirin-containing compounds*—it occurs when it is kept in mucobuccal fold to relieve toothache.
- *Hydrogen peroxide*—concentration greater than 3% can cause epithelial necrosis.
- *Silver nitrate*—it is used in treatment of aphthous ulcer for pain relief. This may cause severe mucosal damage.
- *Toothache drop burns*—such drops contain creosote, guaiacol and phenol derivatives. In this phenol can cause extensive mucosal necrosis and underlying bone loss.
- *Ethyl alcohol burns*—topical application of ethyl alcohol solution which results in sloughing of the oral mucosa. Some of the mouth wash contain 25% ethyl alcohol.

- **Acid burns**—if the rubber dam placement is ineffective then acid used to etch tooth surface may come in contact with the oral mucosa.
- **Ingestion**—chemical burns of the oral cavity can result when the children by mistaken drink household chemical and with suicide attempts by ingestion of caustic material.

Clinical features

- **Symptoms**—the lesion is usually painful.
- **Appearance**—irregularly shaped, white pseudomembrane covered lesion develops (**Fig. 11-7**).
- **Signs**—gentle lateral pressure causes the white material to slide away exposing an exquisitely painful central red ulceration and more adherent patches of white material on the periphery. Diffuse border may present if the burn is more extensive.
- **Cotton roll burns (cotton roll stomatitis)**—cotton roll is used for control of moisture during dental treatment. Sometimes dry mucosa can adhere to cotton roll. While removing cotton roll from the oral cavity epithelium can also be removed along with it. This type of lesion is called as cotton roll burns or cotton roll stomatitis.

Fig. 11-7: Chemical burn showing white pseudomembrane type of lesion.

Diagnosis

- **Clinical diagnosis**—history is very important while coming to clinical diagnosis. If patient gives history of any medicament kept in oral cavity diagnosis of chemical burn can be made.

Differential diagnosis

- **Candidiasis**—in chemical burns there is acute onset, pain and focal area of involvement which is usually not a feature of candidiasis.

Management

- **Prevention**—prevention is best treatment for the chemical burn. Patient should be asked to not to keep tablet in oral cavity for longer period of time.

- **Pain control**—it should be done with a topical anesthetic like dyclonine hydrochloride. Pain relief may result from anesthetic effect of an antihistaminic mouth rinse.
- **Protective coat**—protective coat of emollient paste or hydroxypropyl cellulose film should be applied.
- **Surgical debridement**—when large area of necrosis is present surgical debridement of necroses tissue should be carried out.
- **Antibiotics**—this should be given to prevent secondary infection.

Radiation Mucositis

It is secondary to therapeutic radiation of head and neck cancer develops towards the end of the 1st week of therapy. It occurs if radiation given in excess of 3500 to 4000 rads.

Mucositis occurs when the rate of epithelial growth and repair are affected by radiation, resulting in epithelial thinning, erosion and ulceration.

Clinical Features

- **Age and sex**—most commonly found in children and elderly adults with male predilection.
- **Site**—radiation has more marked effect on rapidly proliferating epithelium and therefore, mucositis involves the non-keratinized mucosa first.
- **Appearance**—there is redness of oral mucosa followed by pseudomembrane formation with large area of oral mucosa covered with grayish, white slough alternating with areas of more severe ulceration (**Fig. 11-8**).
- **Signs**—the first sign of mucositis may be whitish appearance of the mucosa due to hyperkeratinization and intraepithelial edema or a red appearance due to hyperemia.

Fig. 11-8: Radiation mucositis occur due to radiation. Note severe ulceration with pseudomembrane formation on oral mucosa.

- *Acute reaction*—acute reaction occurs during the course of radiotherapy due to direct tissue toxicity. Ulcer resolves over several weeks following the completion of therapy.
- *Chronic reaction*—chronic complication or late radiation reaction occurs due to change in the vascular supply, fibrosis in connective tissue and muscle and change in cellularity of tissues.

Diagnosis

- *Clinical diagnosis*—severe mucosal ulceration with history of radiation will diagnose the condition of radiation mucositis.

Management

- *Mouth rinse*—a soothing mouth rinse such as an antihistaminic with kaopectate will offer pain relief.
- *Good oral hygiene*—it is the most effective treatment for complication of radiation therapy. Once radiation therapy is initiated, all foci of infection from oral cavity should be removed.
- *Betamethasone mouth wash*—high dose of betamethasone mouth wash is very effective treatment for radiation mucositis.
- *Other therapy*—other therapy like topical allopurinol, antimicrobial lozenges, benzydamine, capsaicin, chamomile, dyclonine HCL, milk of magnesia are tried but there is limited success for this therapy.

Uremic Stomatitis

Non-keratotic white lesions caused due to elevated creatinine or blood urea nitrogen. It has been suggested to be consequence of strongly alkaline saliva due to ammonia formation from retained urea secreted in the saliva. Most of the cases of uremic stomatitis occur in acute renal failure.

Types

- *Type I*—generalized or localized erythema with pseudomembrane formation. After removal of pseudomembrane no ulceration is present.
- *Type II*—this is severe form and after removal of pseudomembrane ulceration is present.

Clinical Features

- *Age and sex*—it is common in young and middle aged adults with no sex predilection.
- *Site*—it is predominately seen in buccal mucosa, tongue and floor of mouth.
- *Symptoms*—there is ammoniacal odor to breath. Patient may complain of unpleasant taste and burning sensation in oral cavity.

- *Appearance*—there is extensive pseudomembranous white lesion (**Fig. 11-9**).
- *Signs*—in some cases, there is appearance of ulcers.
- *Shape and size*—oral ulceration varies in size and is irregular in shape and is usually shallow.
- *Oral hairy leukoplakia*—in some cases uremic stomatitis can mimic oral hairy leukoplakia.

Fig. 11-9: White pseudomembrane lesion in patient with acute renal failure seen on buccal mucosa.

Diagnosis

- *Clinical diagnosis*—patient with uremic ulcer will manifest the clinical signs of the uremic syndrome, an ammonia odor of the breath, weight loss, anemia and cardiac arrhythmias confirms the diagnosis of uremic stomatitis.

Management

- *Palliative oral rinse*—ulcer, if painful may be treated by prescribing a palliative oral rinse such as an antihistamine oral suspension with kaopectate.
- *Acidic mouth rinse*—mild acidic mouth rinse like diluted hydrogen peroxide can clear oral lesion.

Candidiasis

It is also called as 'candidosis'. An older name for this disease is 'moniliasis'. Candidiasis is the disease caused by infection with yeast-like fungus *Candida albicans*. Oral involvement is probably the most common manifestation of human candidal infection. It can occur either solely confined to the oral mucosa or as a part of any of the several mucocutaneous candidiasis syndromes.

Classification

There are many classifications for Candidiasis (Tables 11-2 to 11-4). Some of them are listed below. Classifications are made on the basis of clinical presentation, location, etc.

Causative Organisms

It is caused by *Candida albicans* (the yeast-like fungus occurs in yeast and mycelial forms). Other candida species which can cause candidiasis are *Candida stellatoidea*, *Candida tropicalis*, *Candida parapsilosis*, *Candida pseudotropicalis*, *Candida famata*, *Candida rugosa*, *Candida krusei* and *Candida guilliermondii*.

It is present in two forms, i.e. dimorphisms. Yeast form and hyphal form.

Candida albicans is the commonest pathogen of all candida species and it appears as moist creamy colonies and on blood agar as dull gray colonies.

Predisposing Factors (Table 11-5)

- *Changes in oral microbial flora*—marked changes in oral microbial flora may occur owing to administration of antibiotics (broad spectrum), excessive use of antibacterial mouth rinses, xerostomia secondary to anticholinergic agent or salivary gland disease. This

Table 11-2: First classification

Oral candidiasis

Acute

- Acute pseudomembranous candidiasis (thrush)
- Acute atrophic candidiasis (antibiotics sore mouth)

Chronic

- Chronic atrophic candidiasis
 - Denture stomatitis
 - Median rhomboid glossitis
 - Angular cheilitis
- Id reaction
- Chronic hyperplastic candidiasis

Chronic mucocutaneous candidiasis

- Familial CMC
- Localized CMC
- Diffuse CMC
- Candidiasis endocrinopathy syndrome

Extraoral candidiasis

- Oral Candidiasis associated with extraoral lesions orofacial and intertriginous sites (candidal vulvovaginitis, intertriginous candidiasis)
- Gastrointestinal candidiasis
- Candida hypersensitivity syndrome

Systemic candidiasis

- Mainly affect the eye, kidney and skin

Table 11-3: Second classification

Primary oral candidiasis

- *Acute form*
 - Pseudomembranous
 - Erythematous
- *Chronic form*
 - Hyperplastic
 - Erythematous
 - Pseudomembranous
- *Candida associated lesion*
 - Denture stomatitis
 - Angular stomatitis
 - Median rhomboid glossitis
- *Keratinized primary lesion super-infected with candida*
 - Leukoplakia
 - Lichen planus
 - Lupus erythematosus

Secondary candidiasis

- Oral manifestations of systemic mucocutaneous candidiasis (as a result of diseases such as thymic aplasia and candida endocrinopathy syndrome).

Table 11-4: Third classification

Candidiasis of nails and skin

- Candidal onychia
- Candidal paronychia

Candidiasis confined to skin

- Interdigital candidiasis
- Intertriginous candidiasis
- Candidids (monillids)

Candidiasis confined to mucosae

Oral mucosa

- *Acute oral candidiasis*
 - Acute pseudomembranous candidiasis (thrush)
 - Acute atrophic candidiasis (antibiotics sore mouth)
- *Chronic oral candidiasis*
 - Chronic atrophic candidiasis (denture sore mouth)
 - Chronic hyperplastic candidiasis

Gastrointestinal mucosa

- Pharyngeal candidiasis
- Esophageal candidiasis
- Intestinal candidiasis

Respiratory mucosa

- Bronchial candidiasis

Genitourinary mucosae

- Candidal vulvovaginitis

Mucocutaneous candidiasis

Confined to mucocutaneous surface

- *In condition with major immunologic defect*
 - Swiss-type agammaglobulinemia
 - Hereditary thymic dysplasia
 - Di George syndrome
 - AIDS
- *In condition with minor immunological or other systemic defect*
- *Chronic mucocutaneous candidiasis (CMC) syndromes*
 - Familial mucocutaneous candidiasis
 - Candidiasis endocrinopathy syndrome
 - Localized chronic mucocutaneous candidiasis
 - Diffuse chronic mucocutaneous candidiasis
 - Chronic mucocutaneous candidiasis in association with thymoma

Confined to mucocutaneous junctions

- Candidal angular cheilitis
- Perianal candidiasis

Systemic candidiasis

- Candidal endocarditis
- Candidal septicemia
- Candidal meningitis

Table 11-5: Conditions associated with increased vulnerability of oral candidiasis and their mechanism

Category	Condition	Mechanism
Altered local resistance to infection	Poor oral hygiene Xerostomia Recent antibiotics treatment Dental appliance	Promotes organism adherence and colonization Absence of antimicrobial and flushing effect of saliva Inhibits competitive oral bacteria Isolated mucosa from saliva and functional cleansing serve as organism reservoir
Compromised immune system function	Early infancy Genetic immune deficiency AIDS Corticosteroids therapy Pancytopenia	Immune competence has not completely developed Specific humoral or cellular immune defects Deficient cellular immune response Inhibition of immune function Depletion of circulating leukocytes caused by chemotherapy, aplastic anemia and similar hemopoietic disorders
Generalized patient debilitation	Anemia, malnutrition, malabsorption Diabetes mellitus Advanced systemic disease	Epithelial thinning and altered maturation, poor tissue oxygenation Recurring hyperglycemia and mild ketoacidosis Metabolic toxicity or limited blood perfusion of tissue

change will result in inhibition of competitive bacteria resulting in candidiasis.

- *Local irritant*—chronic local irritant (denture, orthodontic appliance and heavy smoke).
- *Drug therapy*—administration of corticosteroids, cytotoxic drugs, immunosuppressive agents and radiation to head and neck.
- *Acute and chronic disease*—acute and chronic disease such as leukemia, lymphoma, diabetes and tuberculosis.
- *Malnutrition states*—malnutrition states such as low serum vitamin A, pyridoxine and iron levels.
- *Age*—age (infancy, pregnancy, old age), hospitalization and oral epithelial dysplasia.
- *Endocrinopathy*—endocrinopathies such as hypoparathyroidism, hypothyroidism and Addison's disease.
- *Immunodeficiency states*—Primary and acquired immunodeficiency state such as hypogammaglobulinemia.
- *Others*—tight and close fitting garments encourage the growth of candida. Areas around the indwelling catheter are also involved.

Thrush or Pseudomembranous Candidiasis

It is the prototype of oral infection caused by yeast-like fungus. It is the superficial infection of upper layer of oral mucous membrane and results in formation of patchy white plaque or flecks on mucosal surface.

Pathogenesis

- *Overgrowth of yeast*—overgrowth of yeast on the oral mucosa leads to desquamation of epithelial cells and accumulation of bacteria, keratin, and necrotic tissue.
- *Formation of pseudomembrane*—this debris combines to form a pseudomembrane, which may adhere closely to the mucosa.

Clinical Features

In infants

- *Age*—in neonates, oral lesions start between the 6th and 10th day after birth.
- *Cause*—infection is contracted from the maternal vaginal canal where *Candida albicans* flourishes during the pregnancy.
- *Appearance*—the lesions in infants are described as soft white or bluish white, adherent patches on oral mucosa which may extend to circumoral tissue.
- *Symptoms*—they are painless and noticed on careful examinations. They may be removed with little difficulty.

In adult

- *Sites*—common sites are roof of the mouth, retromolar area, and mucobuccal fold. But it is common on any other mucosal surface.
- *Sex*—it is common in women as compared to male.
- *Prodromal symptoms*—prodromal symptom like rapid onset of bad taste may be there. Spicy food will cause discomfort.
- *Symptoms*—patient may complain of burning sensation.
- *White plaques*—pearly white or bluish white plaques are present on oral mucosa. They resemble cottage cheese or curdled milk (**Figs 11-10 and 11-11**). Patches are loosely adherent to oral mucosa.
- *Composition of plaques*—it is composed of tangled mass of hyphae, yeast, desquamated epithelial cells and debris.
- *Adjacent mucosa*—Mucosa adjacent to it appears red and moderately swollen.
- *Wiping of patches*—white patches are easily wiped out with wet gauze which leaves either a normal or erythematous area or atrophic area (**Fig. 11-12**). This area may be painful. Deeper invasion by the organism leaves an ulcerative lesion upon the removal of patch.

Fig. 11-10: White plaque resembling as curdled milk present on lip (Courtesy Dr Chole).

Fig. 11-11: Thrush present as white plaque on the tongue.

Fig. 11-12: Red atrophic mucosa seen in patient after adherent patches are removed (Courtesy Dr Chole).

- *Inconspicuous lesion*—in some cases lesions are relatively inconspicuous (not noticeable easily) (Fig. 11-13).
- *Malignant association*—it is occasionally associated with (coexist with) dysplastic or carcinomatous change.

Fig. 11-13: Candidiasis present on the tongue as a diffuse white lesion which is not noticed easily.

Diagnosis

- *Clinical diagnosis*—pseudomembranous lesion which can be scraped off will diagnose candidiasis.

Differential Diagnosis

- *Plaque form of lichen planus*—lesions of thrush can be wiped with the help of gauze.
- *Leukoplakia*—history of recent administration of antibiotics will favor the diagnosis of candidiasis.
- *Genodermatoses*—cytological smear should be taken to confirm the diagnosis.
- *Gangrenous stomatitis*—pseudomembrane is dirty in color and not raised above the surface.
- *Chemical burns*—the superficial white material burns of oral mucosa appears thin and delicate as compared to pseudomembranous candidiasis.

Acute Atrophic Candidiasis

It is also called as '*antibiotics sore mouth*'. When the white plaque of pseudomembranous candidiasis is removed, often red atrophic and painful mucosa remains. It may arise in acute pseudomembranous candidosis after the white plaques have shed yet the infection persists, AIDS patients, in patient receiving prolonged drug therapy: topical steroids or broad spectrum antibiotics and most commonly related to wearing dentures.

Clinical Features

- *Sites*—it can occur at any site but it usually involves the tongue and tissue underlying the prosthesis.

- **Appearance**—in this type, lesion appears as red or erythematous (**Fig. 11-14**) rather than white, thus resembling the pseudomembranous type in which white membrane has been wiped off.
- **Symptoms**—patient usually described vague pain or a burning sensation. If the discomfort is not spontaneous, pain can be elicited by mild abrasive pressure with cotton gauze.
- **Signs**—careful examination reveals a few white thickened foci that rub off leaving a painful surface. Lesion closely resembles erosive lichen planus and erythroplakia.

Fig. 11-14: Acute atrophic candidiasis involving the tongue showing erythematous area (Courtesy Dr Chole).

Diagnosis

- **Clinical diagnosis**—erythematous area with condition causing diminished host resistance will diagnose acute atrophic candidiasis.

Differential Diagnosis

- **Chemical burn**—focal white area that rub off and underlying condition of diminished host resistance favors candidiasis. History of medicament is present.
- **Drug reaction**—identification of condition causing diminished host resistance is reliable differential diagnostic feature of atrophic candidiasis.
- **Syphilitic mucus patches**—discrete small white necrotic lesions on tongue, palate or lip while candidiasis is diffuse. Skin lesion of syphilis is also present.
- **Necrotic ulcer and gangrenous stomatitis**—ulcer is deeper than candidiasis.
- **Traumatic ulcer**—history of trauma is present.

Chronic Hyperplastic Candidiasis

It is also called as '*candidal leukoplakia*' because of its firm

presentation as firm and adherent white patches occurring in the oral mucosa.

Clinical Features

- **Age and sex**—it predominantly occurs in men of middle age or above. The majority of these patients are heavy smokers.
- **Sites**—it occurs on cheek, lip and tongue.
- **Appearance**—candidal leucoplakia is extremely chronic form of oral candidiasis in which firm, and white leathery plaques are found (**Fig. 11-15**).
- **Symptoms**—lesions may persist without any symptoms for years.

Fig. 11-15: Chronic hyperplastic candidiasis showing firm white appearance.

- **Signs**—It does not rub off with lateral pressure. Lesion range from slightly white to dense white (**Fig. 11-16**) with cracks and fissures occasionally present. The borders are often vague, which mimic the appearance of epithelial dysplasia. It may occur as a part of chronic mucocutaneous candidiasis.

Fig. 11-16: Hyperplastic candidiasis showing fissure and crack on the tongue (Courtesy Dr Bhaskar).

Diagnosis

- *Clinical diagnosis*—a firm white leathery appearance seen which cannot rubbed off.

Differential Diagnosis

- *Lichen planus*—characteristic striated appearance, the presence of skin lesion confirm the diagnosis of lichen planus.
- *Hairy leukoplakia*—hyperplastic candidiasis improve with antimycotic treatment while hairy leukoplakia remains unchanged or progresses.
- *Superficial bacterial infection*—microscopic culture.

Id Reaction

A person with chronic candida infection may develop secondary response characterized by localized or generalized sterile vesicopapular rash that is believed to be allergic response to candida antigen (also called as monolids).

Candida Associated Lesion

Denture Stomatitis

It is also called as '*chronic atrophic candidiasis*'. It is common clinical manifestation of erythematous candidiasis. *Candida albicans* is always found in this lesion but the typical white patch of thrush does not usually develop in it. It occurs due to tissue invasion but organism effect of fungal toxin hypersensitivity to fungus.

Clinical features

- *Site*—it is usually found under complete denture or partial denture and found mostly in women and always include palate.
- *Appearance*—it exhibits patchy distribution often associated with speckled curd-like white lesion.
- *Symptoms*—soreness and dryness of mouth.
- *Signs*—palatal tissue is bright red and somewhat edematous and granular. Red patches may be erythematous or speckled. The redness of mucosa is rather sharply outlined and restricted to the tissue actually in contact with the denture (**Fig. 11-17**). The multiple pinpoint foci of hyperemia usually involving the maxilla frequently occurs.

Diagnosis

- *Clinical diagnosis*—an erythematous area under the complete denture will aid in diagnosis of candidiasis.

Differential diagnosis

- *Allergic reaction due to denture base*—it is very rare condition. If there is failure to respond to antifungal therapy then one should suspect allergic reaction.

Fig. 11-17: Denture stomatitis presented as erythematous area in maxillary area.

- *Erosive lichen planus*—skin lesion are present.
- *Dermatitis herpetiformis*—a cytological smear with periodic acid Schiff stain will disclose mycelia.

Management

- Troches containing clotrimazole and Nystatin 4 to 5 times should be applied on the denture after meal and bed time.

Median Rhomboidal Glossitis

There is debate that it is form of chronic atrophic candidiasis but area of anterior 2/3 of tongue affect by median rhomboidal glossitis is frequently followed by candida infection. It is described in detail in Chapter 22: Disease of Tongue.

Angular Cheilitis

It is described in Chapter 23: Diseases of Lip.

Treatment of Oral Candidiasis

Oral candidiasis may be treated either topically or systemically. Treatment should be maintained for 7 days. Response to treatment is often good; oral lesions and symptoms may disappear in a fairly short period (ranging from 2 to 5 days), but relapses are common because of the underlying immunodeficiency. As with other causes of oral candidiasis, recurrences are common if the underlying problem persists:

- *Removal of the causes*—replacement of denture or relining or adding mycostatin suspension below it while insertion in mouth in case of angular cheilitis and denture sore mouth. The denture must be cleaned thoroughly and regularly and should be left out of the mouth at night in hypochlorite solution. Withdrawal or change of antibiotics can be done if feasible.

- **Topical treatment**—topical treatments are preferred because they limit systemic absorption, but the effectiveness depends entirely on patient compliance. Following are most commonly used topical treatment.
 - **Clotrimazole**—it is an effective topical treatment (one oral troche [10-mg tablet]) when dissolved in the mouth five times daily. Used less frequently, one vaginal troche can be dissolved in the mouth daily. This drug has got antibacterial as well as antifungal properties.
 - **1% gentian violet** can be used but it is not ideal because of the superficial necrosis of mucosa and it may produce unsightly staining.
 - **Nystatin preparations**—it includes a suspension, a vaginal tablet, and an oral pastille. Nystatin vaginal tablets (one tablet, 100,000 units, dissolved in the mouth three times a day). Nystatin oral pastille (available as a 200,000-unit oral pastille, one or two pastilles dissolved slowly in the mouth five times a day). Nystatin oral suspension 100,000 units/cc, 1 teaspoon of which is mixed with $\frac{1}{4}$ cup of water and used as oral rinse.
 - **Amphotericin B**—another therapeutic choice is Amphotericin B (0.1 mg/ml). 5 to 10 ml of oral solution is used as a rinse and then expectorated three to four times daily. Elixir containing both tetracycline and amphotericin B may also prove to be beneficial in acute atrophic candidiasis. Addition of triamcinolone acetonide with nystatin can be used in case of angular cheilitis.
 - **Mycostatin cream**—1 lack unit or lactose containing vaginal tablet keeps under the tongue. The addition of absorbable corticosteroids and antibiotic agents to mycostatin cream and ointment accelerate the symptomatic effect. Mycostatin can be used as rinse for 7 to 10 days 3 to 4 times a day.
 - **Idoquinol**—it has antifungal and antibacterial properties. When this is combined with corticosteroid is very helpful in management of angular cheilitis.
- **Systemic treatment**—several agents are effective for systemic treatment.
 - **Nystatin**—it is polyene agents given 250 mg TDS for 2 weeks followed by 1 troche per day for third week. Nystatin has bitter taste, so to avoid patient discomfort. Sucrose or flavoring agents should be added.
 - **Ketoconazole**—it is imidazole derivative and taken as 200-mg tablet with food once daily. Patient compliance is usually good. Careful monitoring of liver function is necessary for long-term use because of reported side effects, including hepatotoxicity. Lack of efficacy of ketoconazole may occur as it requires acidic environment for proper absorption.

- **Fluconazole**—it is a triazole antifungal agent effective in treating candidiasis (100-mg tablet taken once daily for 2 weeks). Several studies suggest fluconazole is effective as a prophylactic agent, although the most effective prophylaxis dosing regimen is still unclear. Numerous reports, however, describe oral and esophageal candidiasis failing to respond to treatment with fluconazole, and in some of these cases investigators isolated resistant strains.
- **Itraconazole**—it (100-mg capsules) may be used for the treatment of oral candidiasis (200 mg daily orally for 14 days). Itraconazole oral suspension is now available (200 mg daily for 2 weeks). Salivary levels of itraconazole are maintained for several hours after administration. Itraconazole is contraindicated in patient taking astemizole, triazolam, midazolam and cisapride.

Chronic Mucocutaneous Candidiasis

Oral candidiasis may also be seen in immunological group of disorders called as mucocutaneous candidiasis. Autosomal recessive pattern is observed in this type of candidiasis. Oral lesions in this are usually thick white plaques which are not rub off.

It is caused by defect in cellular immunity and defect in structure of epidermis. Other factors which are responsible for chronic mucocutaneous candidiasis are diabetes, steroid therapy and in some cases of pregnancy.

Types

- **Chronic familial mucocutaneous candidiasis**—it is an inherited disorder, probably an autosomal recessive disorder and affects both sexes.
- **Chronic localized mucocutaneous candidiasis**—this form occurs early in life with oral mucosal, skin and nail involvement.
- **Endocrinopathy candidiasis syndrome**—in this there is subsequent appearance of hypoparathyroidism, hypoadrenocorticism and other endocrine abnormalities.
- **Chronic diffuse mucocutaneous candidiasis**—lesions involve pharyngeal mucosa and it is diffuse in nature.
- **Chronic mucocutaneous candidiasis in association with thymoma**—rarely patient with thymoma manifest chronic mucocutaneous candidiasis.

Clinical Features

- **Chronic familial mucocutaneous candidiasis**—it is characterized by candidiasis of mouth, nails, and skin. Children under the age of 10 years show superficial candidal infection. Oral candidiasis is chronic hyperplastic exhibiting firm white patches involving either buccal or lingual mucosa.

- *Chronic localized mucocutaneous candidiasis*—there is presence of chronic oral candidiasis and hypoplastic infection of nails fold in infancy. There are white patches characterized by horny masses mainly found on face and scalp. Patient show increase tendency to fungal and bacterial infection in the absence of immunological or genetic defect.
- *Candidiasis endocrinopathy syndrome*—it is also genetically transmitted, characterized by early onset and candida lesion of skin, scalp, nails and mucous membrane. There is occurrence of dental hypoplasia and severe caries. There may be balanitis and vulvovaginitis, keratoconjunctivitis, alopecia and juvenile cirrhosis.
- *Chronic diffuse mucocutaneous candidiasis*—it is of late onset and exhibits extensive raised crusty sheets involving the limbs, groin, face, scalp and shoulders. Mucocutaneous candidiasis is characterized by extensive oral, pharyngeal and often laryngeal involvement. Cutaneous involvement is characterized by raised, crusty proliferative lesions predominately on the skin of face and scalp. These lesions are also called as 'candidal granuloma'. Oral lesions are widespread, proliferative and raised white lesions.
- *Chronic mucocutaneous candidiasis in association with thymoma*—Oral and skin surface are usually involved.

Management

- *Antifungal drugs*—for resistance form of CMC and for systemic candidiasis miconazole (250 mg 6 hourly), 5-flucytosine (200 mg daily) in addition to Amphotericin B is available.
- *Transfusion of transfer factor*—transfusion of transfer factor and transplantation of culture of thymic fragments have been used to correct T. cell deficiency associated with CMC.

Systemic Candidiasis

This term is used when there is presence of both necrotizing inflammation and candida granuloma formation in one or more visceral organ usually as a result of hematogenous dissipation of organism.

Etiology

- *Immunosuppressive patient*—it occurs in immunosuppressive patient as a result of leukemia, lymphoma, steroids, cytotoxic therapy and extensive therapy.
- *Contaminated instrument*—contaminated IV instruments and indwelling catheter may lead to systemic candidiasis.
- *Drugs*—use of contaminated drug, paraphernalia by drug abuses.

- *AIDS*—this is immunological disorder in which systemic candidiasis may occur.

Clinical Features

- *Candidal endocarditis*—it is characterized by fever, dyspnea and edema of congestive cardiac failure. Vascular vegetations of candidal growth often result in embolization to major vessels. The disease is fatal in majority of cases.
- *Candidal meningitis*—it is predominately disease of male children characterized by variable features ranging from stiffness of the neck, hemiplegia and other neurological signs. The finding of Candida in spinal fluid is of diagnostic importance. The condition is fatal in half of the cases.
- *Candidal septicemia*—it occurs in those with severe oral and esophageal thrush. Features include fever, chills, shock and coma. Condition can be fatal if not treated in time.

Management

- Systemic candidiasis requires systemic administration of high doses of *Amphotericin-B* 10 mg QID, *miconazole* and *5-flucytosine*. *Mycostatin* 50,000 unit 8 hourly. Daily use of 200 mg *ketoconazole* for 2 weeks. Side effects are increased liver enzyme, abdominal pain.

Gastrointestinal Candidiasis

An extension of oral infection may occasionally lead to either pharyngeal or esophageal involvement.

Causes

- *Drugs*—long term broad-spectrum antibiotics, corticosteroid therapy and immunosuppressive drugs.
- *Diseases*—leukemia, diabetes and acquired immunodeficiency syndrome.

Clinical Features

- *Symptoms*—it presents acute enterocolitis, diarrhea, as proctitis with anal pruritis of perineal eczematation. Dysphagia, chest pain, and GIT bleeding may be presenting symptoms.
- *Esophageal candidiasis*—esophageal candidiasis with or without gastric ulceration are common forms of GIT candidiasis.
- *Appearance*—it is diagnosed by characteristic appearance of edematous ulcerated mucosa on barium swallow.

Management

- The use of topical and systemic antifungal agents.

Candidal Onychia and Paronychia

It is the candidal infection of nail and of the soft tissue on the sides and at the base of the nail and is common in housewives, nurses, and dishwasher, bartenders, and fruit pickers.

Involved nail show green black discoloration and transverse ridges. Soft tissues surrounding the nails are inflamed and tender.

Treatment is by daily topical application of amphotericin B lotion or nystatin ointment.

Interdigital Candidiasis

It is also called as *erosion interdigitalis*. It commonly involves 3rd and 4th fingers.

It is characterized by pruritic, inflamed, and scaling lesions between fingers. Treatment includes topical application of amphotericin B lotion or nystatin ointment.

Intertriginous Candidiasis

It is the candida infection of skin surface such as waist, groin, armpit, elbows, submammary area, gluteal fold, axilla, and scrotum. Intertriginous candidiasis causes colonization in skin like axilla or submaxillary fold.

Opposing skin surface in these sites, particularly in obese person prevent adequate ventilation and remain moist favoring candidal growth.

Candida has characteristic way of causing dry pustulation with desiccation in lower level of stratum corneum of skin. Lesions are very tender. Lesion spread from affected skin as an area of glaze red skin or an easily detached overlying epidermis i.e. often invaded leaving paper-like fungal lesion along the margin. Satellite lesion may develop around deeper denuded tissue.

Bronchial Candidiasis

It is a chronic infection of bronchial mucosa which may last for years without producing severe discomfort. It mimics chronic bacterial infection of the bronchus and chronic cough with mucoid sputum is common symptoms experienced by the patients.

Diagnosis is established by the demonstration of candida in sputum and through culture studies.

Management includes systemic use of antifungal agents.

Candidal Vulvovaginitis and Balanitis

Candida vulvovaginitis is a common form of candidiasis, which increases during pregnancy, diabetes, and uses of antibiotics. Candidal inflammation of glans penis may occur due to sexual contact. Diabetic women and those on long term drug therapy are prone to develop vaginal infection.

It is characterized by erythematous plaques on the glans penis and around the prepuce. Symptoms usually clear up on topical application of antifungal agents.

Candidiasis with Major Immunological Defect

- *Swiss-type agammaglobulinemia*—it is characterized by severely impaired resistance to infections of all types as a result of failure of thymic development and antibody production. Infants die in the first year of life. Oral candidiasis is a consistent feature of this syndrome.
- *Hereditary thymic dysplasia*—impairment of cell mediated immunity due to thymic dysplasia favors severe viral and candidal infection. Oral candidiasis is predominant feature of this disease.
- *Di George syndrome*—it is characterized by under-developed thymus and parathyroid glands due to a defective development of the 3rd and 4th branchial pouches. Oral candidiasis is a consistent feature of this disease.
- *AIDS*—oral manifestation of AIDS among other features include candidiasis of the oral mucosa, where the candidal infection is opportunistic in nature.

Keratotic White Lesions with no Definite Precancerous Potential

Traumatic Keratosis

It refers to an isolated area of thickened whitish oral mucosa that is clearly related to identifiable local irritant and resolves following elimination of irritant.

Etiology

- *Local irritants*—ill fitting denture, sharp clasp and rough edges of restoration are responsible for traumatic keratosis.
- *Cigarettes smoking*—heavy cigarettes smoking may also lead to this type of lesion.

Clinical Features

- *Sites*—most common sites are lip and buccal mucosa.
- *Appearance*—there is isolated thickened whitish area (**Fig. 11-18**).
- *Glassblower's white patch*—it is variant of traumatic keratosis affecting the cheek and lips, which occur in glass factory.

Diagnosis

- *Clinical diagnosis*—isolated white patch with identified local irritant will diagnose the traumatic keratosis.

Fig. 11-18: Isolated white patch seen on buccal mucosa due to sharp cusp.

- *Laboratory diagnosis*—there is varying degree of hyperkeratosis, parakeratosis and acanthosis.

Management

- *Removal of local irritant*—upon removal of the offending agent, the lesion should resolve within 2 weeks.
- *Biopsy in cases of unhealed lesion*—biopsies should be performed on lesions that do not heal to rule out a dysplastic lesion.

Psoriasis

It is a common dermatological disease characterized by white, scaly papules and plaque on an erythematous base that preferentially affects the extremities and scalp. It is characterized by increased activity of keratinocytes.

Etiology and Precipitating Factors

- *Hereditary*—it has been suggested a possible inheritance pattern, possibly transmitted as simple dominant trait.
- *Infection*— β -hemolytic streptococcal infection often precedes psoriasis.
- *Drugs*—antimalarials, β -blocker and lithium may worsen psoriasis and the rash may 'rebound' after stopping systemic corticosteroids or potent local corticosteroid.
- *Emotion*—anxiety precipitates some exacerbation.
- *Neurogenic factor*—mental anxiety and stress can increase severity of the disease.

- *Trauma*—in areas of skin damage such as scratches or surgical wound.
- *Others*—metabolic disturbances and endocrine dysfunction can also precede psoriasis.

Types (Clinical)

- *Stable plaque psoriasis*—it is most common type. The lesions are red with dry, silvery-white scaling, which may be obvious only after scraping the surface.
- *Guttate psoriasis*—it is seen in children adolescents and may follow streptococcal sore throat. Individual lesions are droplet-shaped, small and scaly.
- *Erythrodermic psoriasis*—the skin becomes universally red and scaly or more rarely just red with very little scale present.
- *Pustular psoriasis*—it is a severe form of psoriasis with eruption of minute pustule with shedding of nails is common.

Clinical Features

- *Age*—it commonly affects adults and arises in 2nd and 3rd decades of life.
- *Sites*—it commonly occurs on extremities, and scalp.
- *Progress*—it is usually chronic with acute generalized exacerbations. It is more severe in winter and less severe in the summer as a result of increase exposure to ultraviolet light.
- *Symptoms*—in some cases, patient may complain of itching.
- *Appearance*—it is characterized by occurrence of small sharply defined, dry papules each covered by delicate silvery scale which appear as a thin layer of mica (Fig. 11-19).
- *Margins and shape*—papules are enlarged at periphery and may form large plaques which are roughly symmetrical (Fig. 11-20).
- *Signs*—after removal of scale the surface of skin is red and dusky in appearance.
- *Auspitz's sign*—if the deep scales are removed one or more bleeding points are seen.
- *Psoriatic arthritis*—this is the complication of psoriasis which can involve the temporomandibular joint.

Oral Manifestations

- *Sites*—oral lesions are reported on lip, buccal mucosa, palate, gingiva and floor of mouth.
- *Appearance*—they appear as plaques, silvery, scaly lesions with an erythematous base.
- *Signs*—sometimes they are multiple papular eruptions which may be ulcerated or as small, papillary elevated lesions with scaly surface.

Fig. 11-19: Thin layer of mica appearance seen in psoriasis patient.

Fig. 11-20: Sharply defined papules seen on face of the patient (Courtesy Dr Parate).

- Usually four types of oral manifestations occur in patient with psoriasis:
 - *The first type* consists of minute well defined gray to yellowish white lesion that is round or oval.
 - *The second type* is characteristic by white, elevated, lacy, circinate lesion on the oral mucosa including the tongue. These eruption parallel those of the skin
 - *The third type* consists of a fiery red erythema of the oral mucosa, including the tongue which is seen in acute form.

- *The fourth type* of oral lesion described in psoriasis is a geographic tongue that occurs most frequently among the patients with psoriasis than without.

Diagnosis

- *Clinical diagnosis*—silvery scale appearance with positive Auspitz's signs will diagnose psoriasis.
- *Laboratory diagnosis*—intraepithelial micro-abscess formation (*Munro abscess*) is seen. There is also test tube rete pegs appearance.

Management

- *Topical agents*
 - *Emollients*—it has modest effect in terms of reducing scale.
 - *Dithranol*—it is gold standard therapy with dithranol. It inhibits proliferation when applied to psoriatic plaques.
 - *Tar*—crude tar is used which is pro-inflammatory and action same as dithranol.
 - *Calcipotriol*—it is vitamin D agonist and it reduces the thickness of plaque.
 - *Retinoid*—it diminishes the induration, scaling and redness of plaque.
 - *Corticosteroids*—use of potent topical corticosteroid on the face or hair margins should be under close and expert medical supervision.
- *Ultraviolet light*—it is mainstay of management of patient with moderate to severe psoriasis. It is used 3-7 times in a week.
- *PUVA (psoralens and ultraviolet A) therapy*—psoralens are natural photosensitizers found in number of plants. It includes clearance to greater degree than any other therapy.
- *Systemic treatment*—three main systemic agents are used, i.e. methotrexate, oral retinoid and cyclosporine.

Focal Epithelial Hyperplasia

It is also called as '*Heck disease*'. It is viral induced oral mucosal hyperplastic response characterized by multiple, more or less papillomatous like lesion.

Etiology

- *Papillomavirus*—it is possibly caused by papillomavirus type 13 and 32.
- *HIV virus*—some lesions may be seen in HIV seropositive patients.

Clinical Features

- *Age and sex predilection*—it occurs predominately in children between ages of 3 and 18 years. There is no sex predilection.

- **Site**—common sites are lip, buccal mucosa, commissures, tongue and less commonly on the gingiva, and anterior facial pillar.
- **Appearances**—it appears as multiple nodular lesions with sessile base. It can occur in cluster or in isolated crops. Some time it is present as flat, slightly raised whitish plaque on roughened surface.
- **Cobblestone appearance**—in some cases these lesions are cluster so closely the entire area appear as cobblestone or fissure appearance.
- **Sign**—they become less conspicuous when the mucosa is stretched. It is non-tender. After drying, the lesion reveals finely granular surface texture.
- **Size**—these lesions are soft having size of 1 to 5 mm in diameter with same color as adjacent mucosa.
- **Color**—they are pale to normal in color.
- **Progress**—they often appear to undergo spontaneous regression after 4 to 6 months.

Diagnosis

- **Clinical diagnosis**—sessile, pedunculated pale color clustered multiple lesions may go in favor of focal epithelial hyperplasia.
- **Laboratory diagnosis**—biopsy will show acanthosis with mild hyperparakeratosis usually present over the surface of lesion.

Differential Diagnosis

- **Condyloma acuminatum**—it is the condition with greatest similarity to focal epithelial hyperplasia. Condyloma acuminatum has got cauliflower like appearance as compared to focal epithelial hyperplasia which has got finely granular surface texture.
- **Tuberous sclerosis**—presence of cutaneous lesion.
- **Darier's disease**—there is presence of cutaneous lesion.

Management

- **Regress spontaneously**—no treatment is necessary as these are harmless lesion and it will regress spontaneously.
- **Surgical excision**—conservative surgical excision may be performed for esthetics purpose.

Oral Genodermatoses

These are also a type of keratotic lesion without increased potential for malignant transformation. They are called genodermatoses as they are genetically determined skin disorders.

White Sponge Nevus

It is oral genodermatose, which was described by Cannon in 1935, hence it is also known as 'Cannon's disease'. It is also called as 'white folded gingivostomatitis', 'congenital leukokeratosis', 'pachyderma oralis' or 'oral epithelial nevus'. It is autosomal dominant disease. It appears to represent a defect in epithelial maturation involving tonofilament formation with impaired normal desquamation of the superficial strata of cells.

Clinical Features

- **Age and sex**—it has no definite sex predilection with children most commonly affected and may be present at birth and may become intense at puberty.
- **Site**—the most common sites are cheek, palate, gingiva, floor of mouth, portion of tongue. It may be widespread and may involve entire mucosa. It can also occur on the mucous membranes of the nose, esophagus, genitalia, and rectum.
- **Appearance**—mucosa appears as thickened and folded or corrugated with soft or spongy texture and a peculiar white opalescent line. It has got soaked through, furrowed or wrinkled appearance.
- **Extent**—the lesion varies in extent from a small patch to involvement of a large area of mucosa.
- **Sign**—friction may strip superficial keratotic area leaving zone of normal looking epithelium or raw area. Ragged white area may be present which can be removed by gentle rubbing without bleeding.

Diagnosis

- **Clinical diagnosis**—diffuse thickened white folded appearance in children on buccal mucosa which doesn't disappear after stretching is typical feature of white sponge nevus.
- **Laboratory diagnosis**—biopsy shows thickened epithelium with hyperkeratosis, and acanthosis. In some cases there is extensive keratosis showing 'basket-weave' appearance.

Differential Diagnosis

- **Leukoedema**—it is only opalescent and white sponge nevus has rough granular and lethargic appearance.
- **Leukoplakia**—unusual in patients under the age of 30 years.
- **Lichen planus**—same as above.
- **Pachyonychia congenita**—presence of nail anomalies as well as skin lesions.

Management

- **No treatment**—there is no specific treatment for this disease but prognosis is very good.

Hereditary Benign Intraepithelial Dyskeratosis

It is also called as 'Witkop-Von Sallmann syndrome'. It is superficially similar to the white sponge nevus in its hereditary pattern but its clinical and microscopic features are different. It is inherited as autosomal dominant trait and there is defect in keratinization characterized by cytoplasmic accumulation of tonofilament with loss of cellular interdigitation and desmosomes.

Clinical Features

- *Age and sex*—it is most commonly seen in children with no sex predilection.
- *Sites*—it is commonly seen in eyes. Superficial gelatinous looking plaques occur on a hyperemic bulbar conjunctiva.
- *Symptoms*—there may be photophobia and blindness cause a by involvement of cornea by plaque formation and scarring.
- *Appearance*—eye is characterized by superficial, foamy, gelatinous white plaque overlying the cornea, sometimes producing temporary blindness.
- *Seasonal variation*—eye lesion shows seasonal variation tending to appear or increase in severity in the springs and disappear.

Oral Manifestation

- *Sites*—they are most commonly seen in buccal mucosa, floor of mouth, ventral and lateral surfaces of the tongue, the gingiva, and palate.
- *Appearance*—it appears generally as white, spongy, macerated lesions of the buccal mucosa with or without folds.
- *Signs*—these lesions vary from delicate, opalescent white membranous areas to a rough, shaggy mucosa.
- *Angle of mouth*—lesion frequently involves the corners of the mouth and appears as soft plaques with pinpoint elevation when the mucosa is stretched.
- *Candidial infection*—in some oral lesions, candidial infection may superimpose.

Diagnosis

- *Clinical diagnosis*—white spongy macerated lesion which is accompanied by eye lesion will diagnosed these conditions.
- *Laboratory diagnosis*—buccal mucosa exhibits thickening of the epithelium with pronounced hydropic degeneration.

Differential Diagnosis

- *White sponge nevus*—eye involvement is not present in case of white sponge nevus.

- *Lichen planus*—Wickham's striae is usually seen.
- *Mucooculocutaneous syndrome*—in this condition oral lesions are ulcerative, bullous or erythematous.

Management

- *Ophthalmologist consultation*—for eye lesion ophthalmologist consultation should be done.
- *Antifungal medication*—it is given in the condition when candidiasis superimposed on oral lesion.

Pachyonychia Congenita

It is also called as 'Jadassohn-Lewandowsky syndrome', 'Jackson-Lawler type'. It is extremely uncommon disease, inherited as an autosomal dominant characteristic with incomplete penetrance.

Clinical Features

- *Age and sex*—it usually occurs shortly after birth with no sex predilection.
- *Sites*—fingernails, toenails, palms, soles, knees, elbows, hands, and feet.
- *Nails*—there is marked thickening, increasing toward the free border with nailbed becoming filled with yellowish keratotic debris, often causing the nail to project upward at the free edge.
- *Hair and cornea*—associated sparse hair and corneal dyskeratosis producing corneal opacities have been reported.
- *Feet*—bullae formation occurs on the feet, and secondary infection of these may lead to crippling deformity.
- *Others*—thickening of the laryngeal commissures, tympanic membrane and nasal mucosa and mental retardation are also reported.

Oral Manifestation

- *Sites*—the buccal mucosa, tongue and lips.
- *Appearance*—they consist of focal or generalized white, opaque thickening of the mucosa (**Fig. 11-21**).
- *Ulcers*—there is frequent oral aphthous ulceration is seen.
- *Angular cheilitis*—in some cases inflammation of angle of mouth is seen.
- *Teeth*—natal teeth are also present.

Diagnosis

- *Clinical diagnosis*—dystrophic nail changes with thickened white appearance.
- *Laboratory diagnosis*—the mucous membrane exhibits an intracellular edema or vacuolization of the spinous cell reminiscent of white sponge nevus.

Fig. 11-21: Thickened white appearance seen on buccal mucosa in pachyonychia congenita (Courtesy Dr Pincha).

Differential Diagnosis

- *White sponge nevus*—in pachyonychia congenita there is fingernail changes in association with oral changes.
- *Lichen planus*—Wickham's striae are seen.
- *Hereditary benign intraepithelial dyskeratosis*—in these disorders there is combination of eye and oral lesion.

Management

- *No treatment*—there is no treatment for this disease.

Porokeratosis

It is also called as '*Mibelli's disease*' and it is autosomal dominant. It is characteristic by faulty keratinization of the skin followed by atrophy.

Clinical Features

- *Age and sex*—the majority of disease begins in early childhood but progression of disease is extremely slow. It appears to occur in males with greater frequency than in females.
- *Sites*—it occurs most commonly in extremities particularly in hands and feet, as well as shoulder, face and neck and the genitalia.
- *Appearance*—it consists initially of crateriform keratotic papules which gradually enlarged to form elevated plaques. In some cases there is ring-like keratotic lesion of the skin with atrophic center.
- *Size*—it ranges in size from a few millimeters to several centimeters.
- *Margins*—the plaques are surrounded by a distinct raised border of epidermal proliferation.
- *Nails*—the nails commonly become thickened and ridged. The central portion of the lesions ultimately becomes atrophic, leaving permanent scarring.

Oral Manifestation

- *Site*—it is most commonly seen on upper lip and palate.
- *Appearance*—there is numerous small slightly opalescent rings and serpiginous and hyperemic border studded over the palate.

Diagnosis

- *Clinical diagnosis*—thickened and ridge nails with opalescent palatal lesion.
- *Laboratory diagnosis*—the elevated horny margin of the lesion exhibits hyperkeratosis and acanthosis with a deep groove filled with parakeratin.

Management

- *No treatment*—there is no treatment for the disease except for removal of individual lesions.

Keratosis Follicularis

It is called as '*Darier's disease*', '*Darier-White disease*'. It is autosomal dominant trait. A lack of cohesion among the surface epithelial cells is characterized of this disease.

Clinical Features

- *Age and sex*—it is usually manifested during childhood or adolescence and has equal sex distribution.
- *Sites*—they are generally distributed above the forehead, scalp, neck, and over the shoulders.
- *Cutaneous lesion*—the cutaneous lesion appear small, firm papules (Fig. 11-22).
- *Color*—they are red when they first appear but characteristically become grayish brown or even purple later.
- *Signs*—it can ulcerate and crust over.

Fig. 11-22: Erythematous papules seen on trunk of patient in case of keratosis follicularis (Courtesy Dr Pincha).

- *Skin fold lesion*—in the skin fold the lesion tend to be coalescing and produce verrucous or vegetating macerated, foul smelling masses.
- *Nail changes*—characteristic nail changes are consisting of splintering, fissuring, longitudinal streaking and sublingual keratosis.

Oral Manifestation

- *Sites*—keratotic papule occur on oral mucosa particularly on hard and soft palate, gingiva, tongue have whitish appearance.
- *Signs*—they are multiple whitish papules which feel rough upon palpation. In some cases it has been described as rough, pebbly areas with verrucous white plaque or as having cobblestone appearance. Papules become confluent as disorder progress.

Diagnosis

- *Clinical diagnosis*—erythematous papular lesion on skin with white plaque lesion in oral cavity.
- *Laboratory diagnosis*—dyskeratosis is characterized by typical cells called *corps ronds and grains* (cell within cells).

Differential Diagnosis

- *White sponge nevus*—oral lesion of keratosis follicularis is multipapular or cobblestone appearances as compared to more diffuse or plaque-like pattern of white sponge nevus.
- *Pyostomatitis vegetans*—biopsy will afford a definite diagnosis.

Management

- *Sunscreen*—photosensitive patient should use protective sunscreen.
- *Systemic retinoid*—this is given in case of severely affected patient.

Warty Dyskeratoma

It is also called as 'isolated Darier's disease' which bears histologic similarity to keratosis follicularis but it presents as single isolated focus.

Clinical Features

- *Age and sex*—it usually occurs in older age group with male predominance.
- *Site*—the skin lesion occurs on face, scalp, neck and upper chest.
- *Appearance*—they appear as elevated nodules, umbilicated, with raised borders and varying in color from yellow or brown to gray or black (Fig. 11-23).

- *Size*—they appear as invariably single lesion varying in size from 1 to 10 mm in diameter.
- *Signs*—purulent drainage as well as bleeding occurs in some cases.

Fig. 11-23: Umbilicated nodule seen in warty dyskeratoma (Courtesy Dr Bhaskar Patle).

Oral Manifestation

- *Sites*—it is very rare and if present found most commonly on the alveolar ridge and palate.
- *Appearance*—it appears as small whitish area of the mucosa with a central depression.
- *Focal acantholytic dyskeratosis*—it is variant of warty dyskeratoma in which two or three discrete lesion arising adjacent to one another.

Diagnosis

- *Clinical diagnosis*—whitish area with central depression with skin nodule will aid in diagnosis.
- *Laboratory diagnosis*—biopsy shows central orthokeratin or parakeratin core. Epithelium shows a suprabasilar separation resulting in a cleft-like space containing acantholytic and benign dyskeratotic cells.

Differential Diagnosis

- *Keratoacanthoma*—it can attain dimension upto 1-2 cm while warty dyskeratoma are usually small. Keratoacanthoma fails to exhibit a smooth round border.
- *Molluscum contagiosum*—biopsy may require making the diagnosis.

Management

- *Conservative surgical excision*—it should be treated by surgical excision.

Pseudoxanthoma Elasticum

It is autosomal recessive and the basic defect involves the structure of elastin, making it susceptible of calcification. It is rare hereditary connective tissue disorder, characterized by generalized degeneration of the elastic fibers with a broad phenotypic expression. The clinical picture consists mainly of cutaneous, ocular, and vascular manifestations.

Clinical Features

- *Age and sex*—although widely variable, the age of onset averages 13 years with no predilection for sex.
- *Sites*—raised yellowish papules develop on areas of thickened, coarsely grained skin especially around the mouth, neck, axilla, elbows.
- *Appearance*—brownish gray streaks of the optic fundus (angioid streaks), recurrent gastrointestinal hemorrhage, weak pulse, and failing vision.
- *Cutaneous lesions*—the typical cutaneous lesions are small yellowish papules or larger coalescent plaques with an appearance similar to plucked chicken skin. More severely affected skin results in hanging, redundant folds.

Oral Manifestations

- *Sites*—mucous membranes, mainly of the inner aspect of the lower lip is affected.
- *Hound dog appearance*—skin around mouth becomes redundant, producing a 'hound dog' appearance.
- *Lip*—lower lip exhibits yellowish intramucosal nodule.

Diagnosis

- *Clinical diagnosis*—yellowish lesion seen on skin with hound dog appearance.
- *Laboratory diagnosis*—biopsy shows intramucosal nodules showing large number of thickened and twisted elastic and collagen fibers.

Management

- *No specific treatment*—at present, no specific treatment exists. The knowledge, however, of the potential complications may lead physicians to take some necessary precautions.

Hyalinosis Cutis et Mucosa Oris

It is also called as 'lipoid proteinosis' or 'Urbach-Wiethe syndrome'. It is autosomal recessive trait, characterized by subdermal and submucosal infiltration of a hyaline glycoprotein material.

Clinical Features

- *Age and sex*—it is mostly seen in young adults with no sex predilection.
- *Sites*—it is common in mucosal tissue, skin, vessel walls, larynx, and brain. It is also seen in face, eyelids and neck.
- *Symptoms*—as laryngeal mucosa and vocal cord are affected, infant may not be able to make crying sound. There is also development of hoarse voice during early childhood.
- *Brain*—there may be calcification of dorsum sellae.
- *Cutaneous lesions*—it commences as vesicles, upon healing acneform scars develop. There is also thickened furrowed appearance of skin.

Oral Manifestation

- *Sites*—most commonly affected area is lower lip. It can be seen on tongue, buccal mucosa.
- *Appearance*—affected tissue becomes infiltrated with yellowish white elevated pea sized plaque which gradually increased in size in puberty.
- *Symptoms*—restriction of oral function such as saliva flow, tooth eruption, and swallowing.
- *Angle of mouth*—radiating tissue may appear at angle of mouth.
- *Tongue*—tongue become firm and large and bound to floor of mouth. The dorsum of tongue may losses its papilla and ulcer may develop.
- *Gingiva*—diffuse hyperplastic appearing gingival infiltration is present.
- *Teeth*—there is hypodontia of maxillary lateral incisors and premolars.

Diagnosis

- *Clinical diagnosis*—aceneform scar with hypodontia, xerostomia, and delayed tooth eruption.
- *Laboratory diagnosis*—biopsy shows diffuse hyalinization with prominent hyaline perivascular cuffing. These deposits are PAS positive and show equivocal reaction for amyloid.

Differential Diagnosis

- *Focal epithelial hyperplasia, Cowden syndrome and amyloidosis*—it may show similar clinical features. A dermatological examination should be performed. Biopsy should be performed to confirm the diagnosis.

Management

- *Gingivectomy*—it is recommended when diffuse hyperplastic appearing gingival infiltration is present.

- *Debulking of tissue*—debulking of mucosal lesion may be necessary in cases when it affects the laryngeal mucosa causing difficult breathing.

Oral Premalignant Lesions and Conditions

Concept of Precancer

It is applied that altered state of tissue which often, but not always, has high potential to undergo malignant transformation. Some benign lesions or conditions, for varying length of time, also generally precede oral cancer. Interestingly, these lesions or conditions share the same etiological factors with oral cancer, particularly the use of tobacco and exhibit same site and habit relationship. Many of them show high potential to become cancer and are therefore termed as pre-cancerous lesion.

It is especially important to remember that a premalignancy is not guaranteed to eventually transform into cancer, as is often but erroneously believed. Individual with oral pre-cancer has 69 times greater risk of developing oral cancer as compared to tobacco users who do not have pre-cancer.

Oral pre-cancer is distinguished into the following:

- *Pre-cancerous lesion*—it is defined as a morphologically altered tissue in which cancer is more likely to occur, than its apparently normal counter parts. For example
 - Leukoplakia
 - Erythroplakia
 - Mucosal changes associated with smoking habits
 - Carcinoma *in situ*
 - Bowen disease
 - Actinic keratosis, cheilitis and elastosis.
- *Pre-cancerous condition*—it is defined as a generalized state or condition associated with significantly increased risk for cancer development. For example
 - Oral submucous fibrosis (OSMF)
 - Syphilis
 - Sideropenic dysplasia
 - Oral lichen planus
 - Dyskeratosis congenita
 - Lupus erythematosus.

Precancerous Lesions

Leukoplakia

The term leukoplakia originates from two Greek words—*leuko* i.e. white and *plakia* i.e. patch. It is defined as any white patch on mucosa, which cannot be rubbed or scraped off and which cannot be attributed to any other diagnosable disease. The white color of results from thickened surface keratin layer.

Definition by WHO—It is a whitish patch or plaque that cannot be characterized, clinically or pathologically, as any other disease and which is not associated with any other physical or chemical causative agent except the use of tobacco.

Classification

According to clinical description

- *Homogenous*—it is completely whitish lesion.
 - *Flat*—it has smooth surface.
 - *Corrugated*—like a beach at ebbing tide.
 - *Pumice like*—with a pattern of fine lines (cristae).
 - *Wrinkled*—like dry, cracked mud surface.
- *Non-homogenous*
 - *Nodular or speckled*—characterized by white specks or nodules on erythematous base.
 - *Verrucous*—slow growing, papillary proliferations above the mucosal surface that may be heavily keratinized. Extensive lesion of this type is called as 'oral florid papillomatosis'.
 - *Ulcerated*—lesion exhibits red area at the periphery of which white patches are present.
 - *Erythroleukoplakia*—leukoplakia is present in association with erythroplakia.

According to etiology

- Tobacco induced
- Non-tobacco induced.

According to risk of future development of oral cancer

- **High risk sites**
 - Floor of mouth
 - Lateral or ventral surface of tongue
 - Soft palate
- **Low risk sites**
 - Dorsum of tongue
 - Hard palate
- **Intermediate group**
 - All other sites or oral mucosa

According to histology

- Dysplastic
- Non-dysplastic

According to extent

- Localized
- Diffuse

According to Banoczy

- *Leukoplakia simplex*—a uniform raised plaque formation, varying in size, with regular edges. It corresponds to homogenous type of leukoplakia.
- *Leukoplakia erosiva*—a lesion with slightly raised, rounded, red and/or whitish excrescence, that may be described as granules or nodules.
- *Leukoplakia verrucosa*—it is characterized by verrucous proliferation raised above the mucosal surface.

Etiopathogenesis (Fig. 12-1)**Local factors**

- **Tobacco**—it refers to dried leaves of nicotina tabacum. Tobacco is used widely in two forms: *Smokeless tobacco* (chewable tobacco and oral use of snuff) and *smoking tobacco* (cigar, cigarette, bidi and pipe).
 - **Smokeless tobacco**—when tobacco is chewed, various materials leach out of it, such as tobacco tars and resins. These are the extracts of tobacco, containing various chemical constituents such as nitrosomornicotine, nicotine, pyridine, and picoline and collidin. All these chemical constituents as well as the alkaline pH of snuff (8.2 to 9.3) act as local irritants and are related to the alterations of mucosa. Smokeless tobacco is believed to result in chemical damage that produces sub-lethal cell injury within the deeper layers of oral epithelium. This in turn induces concomitant epithelial hyperplasia. Smokeless tobacco often leads to tobacco pouch keratosis rather than true leukoplakia.
 - **Smoking tobacco**—smoking tobacco is harmful as this smoke contains polycyclic hydrocarbons, betanaphthylamine, nitrosamines, carbon monoxide, nicotine, etc. which act as source of irritation. The heat produced by smoking tobacco also plays a major

Fig. 12-1: Diagrammatic representation of etiology of leukoplakia.

role. Exposure to heat results in alteration of tissue. The initial signs of heat induced alteration of tissue are increased reddening and stippling of mucosal surface. As the use of irritant continues with the exposure to heat, minute white and red striations are formed and the tissue surface may appear slightly swollen. The striations may be caused by increased capillary proliferation and keratin formation. With continued irritation, the lesion precipitates with circumscribed configuration.

- **Alcohol**—the prevalence of leukoplakia is higher among the regular and occasional drinkers than the non-drinkers. It causes irritation and burning sensation of oral mucosa, when applied locally. Alcohol facilitates the entry of carcinogen into exposed cells and thus alters the oral epithelium and its metabolism. But most alcohol consumers use tobacco in some form or the other.
- **Sanguinaria**—this is herbal extract used in toothpaste and mouth rinse. It can cause true leukoplakia and it is more commonly seen in maxillary vestibule or on alveolar mucosa.
- **Chronic irritation**—continuous trauma or local irritation in the oral cavity is suspected as a causative agent for leukoplakia. The source of irritation or trauma may be

any viz. malocclusion, ill fitting dentures, sharp broken teeth, hot spicy food, root piece etc. The usual site to such irritation is the buccal mucosa and less often the alveolar ridge. Chronic irritation must be intense enough to induce surface epithelium to produce and retain keratin. Leukoplakia is a protective reaction of the traumatized mucosa against chronic irritation. But now-a-days it has been observed that maximum lesion due to mechanical irritation are frictional keratosis with very low precancerous potential.

- **Candidiasis**—the presence of *Candida albicans* has been reported very frequently in association with leukoplakia, more commonly with nodular type. *Candidial leukoplakia* may be associated with other local factors, such as tobacco smoking, denture wearing or occlusal friction. Tobacco smoking may result in candidal colonization because of increased keratinization, reduced salivary immunoglobulin-A concentration or depressed polymorphonuclear leukocyte function (**Fig. 12-2**).
- **Electromagnetic reaction or galvanism**—Galvanism is the generation of current due to difference in the electrical potential of two dissimilar metals. Galvanic current may arise in mouth between dissimilar, opposing or adjacent metallic restorations. Patient's complaint may range from a mere metallic taste to persistent pain, due to chronic inflammation of adjacent oral mucosa to even neuralgic pain. These mucosal changes may promote malignant transformation of leukoplakia.

Fig. 12-2: Pathogenesis of candidial leukoplakia.

Regional and systemic factors

- **Syphilis**—it is regarded as a predisposing factor for the development of leukoplakia. White patches are often seen on tongue in tertiary syphilis. Spirochete, the causative agent for syphilis has predilection for the actively mobile tissues of tongue. These tissues are heavily involved during secondary stage of syphilis which leads to diffuse vasculitis and progresses to obliterative endarteritis, eventually resulting in a circulatory deficiency to the lingual papillae. This causes atrophy of filiform and fungiform papillae and results in bald, smooth lingual surface. Shrinkage of the lingual musculature may also occur resulting in a wrinkled surface. With the protective papillae missing, the dorsum of tongue is left extremely susceptible to oral irritation and leukoplakia frequently develops on it. Leukoplakic involvement may be minor or severe and it may be diffuse or localized. In many cases, leukoplakia is of dysplastic variety. Carcinoma of tongue frequently develops in such cases of leucic glossitis.
- **Vitamin deficiency**—deficiency of vitamin A is known to produce metaplasia and keratinization of certain epithelial structures. Hence, it may be causative factor for leukoplakia. Patients with leukoplakia show lower serum levels of vitamin A. Vitamin B complex deficiency has also been suggested as a predisposing factor. It might be related to alteration in the oxidation pattern of the epithelium, making it more susceptible to irritation.
- **Nutritional deficiency**—sideropenic anemia and other nutritional deficiency can be some predisposing factors for the occurrence of leukoplakia.
- **Xerostomia**—some conditions which can cause xerostomia may lead to leukoplakia. These conditions are salivary gland diseases, anticholinergic drugs and radiation.
- **Hormones**—it is difficult to demonstrate significance of male and female sex hormone deficiency and endocrine dysfunction in the etiology of leukoplakia.
- **Drugs**—anti-cholinergic, anti-metabolic drugs and systemically administered alcohol may predispose for the occurrence of leukoplakia.
- **Virus**—two types of viruses have been linked with leukoplakia viz. herpes simplex and human papilloma virus. A specific increase in cell mediated immunity to HSV was observed in dysplastic leukoplakia. HPV associated antigen has also been demonstrated in cases of leukoplakia. These viruses are believed to induce mucosal changes by altering the DNA and chromosomal structure of the cells and by inducing proliferation of such altered cells.
- **Idiopathic (cryptogenic) leukoplakia**—in a small proportion of cases, no underlying cause has been found. Such lesions are termed as idiopathic (cryptogenic) leukoplakia. These lesions have higher potential for malignant transformation.

Clinical Features

- *Sex and age distribution*—it occurs more commonly in older age group, i.e. 35 to 45 years and above. Males are affected more frequently than females, due to direct consequence of tobacco habit.
- *Common sites*—it can occur anywhere on the oral mucosa. Buccal mucosa (**Fig. 12-3**) and commissures (**Fig. 12-4**) are more commonly involved. Lip lesions are more common in men and tongue lesions are more common in women. The involvement of various sites depends upon the type of tobacco habit. Sometimes in edentulous patient alveolar ridge can be involved (**Fig. 12-5**).
- *Commissural leukoplakia* (**Fig. 12-6**)—the lesion is regarded as 'commissural', if it extends posteriorly from labial commissure over a distance of about 2 cm, in triangular shape. In buccal sides it involves the central zone of

Fig. 12-3: Leukoplakia occurring on the buccal mucosa.

Fig. 12-4: Leukoplakia present at commissural region.

Fig. 12-5: Leukoplakia occurring on alveolar region in edentulous patient.

buccal mucosa in the molar region and along the occlusal line. In males, commissural involvement occurs more frequently than buccal one with the latter being the commoner site in females.

Fig. 12-6: Commissural leukoplakia presenting as triangular shaped lesion (Courtesy Dr Chole).

- *Locations in descending order of frequency of involvement*—commissures, buccal mucosa, lips, tongue, palate, and alveolar ridge, floor of mouth, soft palate and gingiva.
- *Sublingual keratosis*—it refers to leukoplakia occurring in floor of mouth and ventral surface of tongue.
- *Ebbing tide type*—some leukoplakia that occur in the floor of the mouth are referred to as 'ebbing tide' type since they appear similar to the undulations left on the sand by the ebbing tide. It occurs due to loose binding and consequent movement of the mucosa in the floor of mouth.

- **Extent**—the extent of involvement may vary from small, well-localized, irregular patches to diffused lesions involving considerable portion of oral mucosa (**Fig. 12-7**). Multiple areas of involvement are not uncommon.

Fig. 12-7: In this leukoplakia, considerable portion of oral mucosa is involved.

- **Color**—lesion may be white or yellowish white (**Fig. 12-8**), but with heavy use of tobacco lesion it may assume brownish color.
- **Surface**—the surface of the lesion is often finely wrinkled or shriveled in appearance and may feel rough on palpation.

Fig. 12-8: Yellowish white color of leukoplakia seen on buccal mucosa. Surface seen as wrinkled (Courtesy Dr Suwas Darvekar).

- **Symptoms**—some patients may report a feeling of increased thickness of mucosa. Those with ulcerated and nodular type may complain of burning sensation. Enlarged cervical lymph nodes may be a single occurrence of metastasis.

Clinical Types

- **Pre-leukoplakia or mild or thin leukoplakia**—a different entity termed as 'pre-leukoplakia' has been distin-

guished. It is a low grade or very mild reaction of the mucosa appearing as grayish white but not completely white lesion with slight lobular pattern. Their margin can be well demarcated or it blends with the adjacent normal mucosa. These lesions are soft, translucent and thin (**Fig. 12-9**).

Fig. 12-9: Mild or thin type of leukoplakia seen in buccal mucosa in posterior region.

- **Homogenous or thick leukoplakia**—it is also called as *leukoplakia simplex*. It accounts for 84% of cases. Leukoplakia seen amongst clay pipe smokers and betel quid chewers are generally of homogenous type. They have no red component.
 - **Appearance**—usually, localized lesions of extensive white patches present a relatively consistent pattern throughout (**Figs 12.10A and B**). However, sometimes the surface lesion may be described as corrugated, with pattern of fine lines, or wrinkled or papillomatous surface.
 - **Size and margin**—it is characterized by raised plaque formation consisting of single or group of plaques varying in size with irregular edges.
 - **Color**—they are usually white in color but may be yellowish white or yellow.
- **Ulcerated leukoplakia**—it occurs in 13% of cases. It is characterized by red area, which at times exhibit yellowish areas of fibrin, giving the appearance of ulceration. White patches are present at the periphery of the lesion (**Fig. 12-11**). Sometimes, it is associated with pigmentation of varying intensity, usually on the periphery of the lesion. Heat produced during smoking also contributes to the occurrence of pigmentation.
- **Nodular leukoplakia**—it is also called as '*leukoplakia erosiva*' or '*speckled leukoplakia*'. It is a mixed red white lesion in which small keratotic nodules are scattered over an atrophic patch of oral mucosa. Nodules may be pinhead sized or even larger (**Fig. 12-12**). It has got a high malignant potential.

Figs 12-10A and B: Homogenous leukoplakia showing thick white patches on buccal mucosa (Courtesy Dr Parate).

Fig. 12-11: Ulcerated type of leukoplakia showing white patches at periphery in the buccal vestibule. Patient is also having leukoplakia at the commissural region extending into buccal mucosa.

- **Verrucous leukoplakia or verruciform leukoplakia**—it is also called as '*leukoplakia verrucosa*'. It is characterized by verrucous proliferation above the mucosal surface. These lesions demonstrate sharp and blunt projection (Fig. 12-13). These projection are heavily keratinized.

Fig. 12-12: Nodular leukoplakia showing pinhead size nodule in retromolar area.

Fig. 12-13: Verrucous leukoplakia showing exophytic lesion present on the tongue (Courtesy Dr Parate).

They may be accompanied by homogenous leukoplakia on other oral mucosal surfaces.

- **Proliferative verrucous leukoplakia (PVL)**—verrucous leukoplakia can become more exophytic with development of multiple keratotic plaques with roughened surface projection (Fig. 12-14). PVL has got strong female predilection and is present in patient who don't use tobacco. It can spread and involve adjacent mucosa. As the disease progress it transforms into a lesion that is clinically and microscopically identical to verrucous carcinoma or squamous cell carcinoma.
- **Erythroleukoplakia**—in some lesion of leukoplakia red component is present. This intermixed lesion is called as erythroleukoplakia

Staging of Leukoplakia

According to size, clinical aspect and pathological features

- **Size**—it is denoted by L
 - L_1 —size is less than 2 cm.
 - L_2 —size is in the range of 2-4 cm.

Fig. 12-14: Proliferative verrucous leukoplakia showing multiple keratotic clefts in anterior region.

- L_3 —size is more than 4 cm.
- L_x —size is not specified.
- **Clinical aspect**—it is denoted by C
 - C_1 —homogenous
 - C_2 —non-homogenous
 - C_x —not specified
- **Pathological features**—it is denoted by P.
 - P_1 —no dysplasia
 - P_2 —mild dysplasia
 - P_3 —moderate dysplasia
 - P_4 —severe dysplasia
 - P_x —not specified
- **Site**—site of leukoplakia
 - S_1 —all sites excluding floor of mouth, tongue
 - S_2 —floor of mouth and tongue
 - S_3 —not specified.

Sharp staging

- **Stage I**—Earliest lesion—non-palpable, faintly translucent, white discoloration.
- **Stage II**—Localized or diffused slightly elevated plaque of irregular outline. It is opaque white and may have fine granular texture.
- **Stage III**—Thickened white lesion showing induration and fissuring.

Diagnosis

- **Clinical diagnosis**—clinically any white patch with history of tobacco chewing which cannot be rub off is the diagnostic indicator for leukoplakia.
- **Laboratory diagnosis**—in biopsy you can see *hyperorthokeratosis, hyperparakeratosis, acanthosis of epithelium, epithelial dysplasia, liquefaction degeneration basal cell hyperplasia*. Scanning electron microscopy will show epithelial dysplastic changes.

Malignant Potential

The term malignant transformation is used to denote development of oral cancer from pre-existing leukoplakia. Malignant transformation occurs in 0.3% to 10% of cases.

It is higher in women (6%) than men (3.9%), due to involvement of endogenous factors. Leukoplakia associated with chewing habit of tobacco shows higher rate of transformation as compared to others. In buccal mucosa and commissure region 1.8% malignant transformation occurs. In lip and tongue region 16% to 38.8% malignant transformation occurs. Nodular dysplasia has higher risk of malignant transformation than other clinical types. Idiopathic leukoplakia and candida associated leukoplakia also come under high risk.

If following features are present there is a high risk of malignant transformation:

- Persistence of lesion for several years.
- Female patient
- Lesion situated on the margins, base of tongue and floor of mouth
- Erosive lesions.
- Combination of above factors.

Differential Diagnosis

- **Lichen planus**—distinguished by the often occurrence of multiple lesions and presence of 'Wickham's striae'.
- **Chemical burn**—history is important in chemical burn.
- **Syphilitic mucus patches**—other features like split papule or condyloma latum may be present.
- **White sponge nevus**—occurs soon after birth or at least by puberty and is widely distributed over the oral mucus membrane. Familial pattern is seen, in contrast to leukoplakia which occurs over 40 years of age and not so disseminated throughout the oral cavity.
- **Discoid lupus erythematosus**—central atrophic area with small white dot and slightly elevated border zone or radiating white striae.
- **Psoriasis**—Auspitz's sign is positive and skin lesions are also present.
- **Leukoedema**—classically occurs on buccal mucosa covering most of the oral surface of cheek and extending onto labial mucosa. Faint milky appearance with folded and wrinkled pattern as compared definite whiteness of leukoplakia.
- **Hairy leukoplakia**—corrugated leukoplakic lesion occurring on lateral and ventral surface of tongue in patients with AIDS or ARC (AIDS related complex).
- **Verruca vulgaris**—commonly occurs in the oral cavity as small, raised white lesion, more than 0.5 cm in diameter as compared to verrucous leukoplakia which is larger and surrounded by inflamed mucosa.

- *Verrucous carcinoma*—lesions are elevated (exophytic).
- *Cheek biting lesion*—careful history elicits the cause and promotes proper diagnosis.
- *Electrogalvanic white lesion*—disappears when different metal restorations are replaced with composite restoration or when teeth are extracted.

Management

Elimination of etiological factors

- *Prohibition of smoking*—patient should be asked to cease smoking immediately. Many cases of leukoplakia get regress after smoking is ceased.
- *Removal of chronic irritant*—dentist should remove sharp, broken teeth.
- *Elimination of other etiological factors*—other etiological factors like syphilis, alcohol, dissimilar metal restoration etc. should be eliminated.

Conservative treatment

- *Vitamin therapy*—it has a protective effect on the epithelium. Daily requirement is 4000 IU. It is given orally, parentally or topically. Therapeutic dose—75000-300000 IU for 3 months. Vitamin A may be used topically after painting the lesion with podophyllin solution (it inhibit mitosis).
- *Vitamin A + vitamin E*—this therapy is given to inhibit metabolic degradation.
- *13-cis-retinoic acid*—It is a synthetic analogue of vitamin A; usually given in high doses of 1.5 to 2 mg/kg body weight for 3 months. If relapse occurs then low doses of 13-cis-retinoic acid 0.5 mg/kg body weight are given for 9 months. It may be given with β carotene (this drug may produce a variety of toxic effects which include facial erythema, dryness, peeling of skin, conjunctivitis and hypertriglyceridemia).
- *Antioxidant therapy*—considerable data shows that β -carotene supplementation can be beneficial for treatment of oral leukoplakia.
- *Vitamin A palmitate*—Short-term treatment with vitamin A palmitate along with aromatic retinoid of all trans -B-A vitamin acid plus, B-cis-B-A vitamin acid may show healing and improvement.
- *Nystatin therapy*—It is given in candidial leukoplakia. 500,000 IU twice daily plus 20% borax glycerol or 1% gentian violet or mouth rinses with chlorogen solution.
- *Vitamin B complex*—it is given as supplement in cases of commissural and lingual lesion.
- *Antimycotic preparation*—the antimycotic preparation can hasten and pimafucin have also been effective.
- *Panthenol*—panthenol lingual tablet and oral spray may be used against glossitis and glossodynia, in case of tongue lesion.
- *Estrogen*—in some cases, administration of estrogen can be helpful.

Surgical management

To give proper treatment, microscopic examination is necessary for which biopsy is taken. The most meaningful sites for taking biopsy specimen are the areas that display greater surface irregularities such as cracks and fissures and those associated with erythematous areas.

- *Conventional surgery*—you should make an incision around the lesion including safe margins. The incision should be deep and wide. Affected area is then undermined and dissected from the underlying tissue. Sliding mucosal flap is prepared for covering the wound. Fine iris scissors and skin hook should be used to decrease trauma. Fairly extensive undermining of the mucosal flap is necessary so that when it is advanced into position, there will be minimum amount of tension. Excessive tension will restrict circulation and can result in necrosis. After proper mobilization of the mucosal flap, it is advanced and multiple interrupted black silk sutures are used. Approximate the free edges. Postoperative application of ice bags to the site is advised to minimize bleeding and swelling.
- *Cryosurgery*—tissue is exposed to extreme cold to produce irreversible cell damage. Cell death occurs at -20 degree Celsius. Disc type probe (cryo probe) refrigerated by liquid nitrogen or pressurized nitrogen oxide is used. Incorporated in the probe is re-warming device, thus tissue can be rapidly frozen and thawed as required. The probe is applied to the surface lesion, which is moistened by water-soluble jelly. It produces very low temperature in tissue. First freeze for 1 minute, followed by 5 minute thaw. 1 minute freeze and then administered. Freezing produces white area of necrosis. The process is repeated two to three times to achieve maximum destruction. Freezing induces crystal formation within the cell and intracellular spaces. When cooling rates are rapid, intracellular ice crystal may rupture cell membrane and cell death can occur. Slower cooling produces large ice crystals in the space between cells. As the crystals grow, water is removed from neighboring cells, leading to an increased concentration of the electrolytes. These soon reach toxic levels initiating cell death by osmotic shock when thawing commences. Cell is also killed by change in microvasculature of the part being exposed to cryosurgery.
- *Fulguration (electrocautery and electrosurgery)*—It is a technique in which there is destruction of tissues by high voltage electric current and the action is controlled by movable electrode. Advantages of this are its ability to coagulate lesion and provide easy control of hemorrhage. Disadvantages are tasteless (foul) odor, hazards of explosion, need for profound local anesthesia and sometimes general anesthesia, slow healing process, pain and scarring.

LASER

LASER stands for light amplification of stimulated emission of radiation. CO₂ lasers are most commonly used in oral lesions due to their great affinity for any tissue with high water content and their minimum penetration depth, i.e. 0.2 to 0.3 mm in oral tissue. CO₂ laser contain CO₂, nitrogen and helium gases

- **Biopsy**—in performing incisional or excisional biopsy in cases of leukoplakia, CO₂ laser is used as precise cutting tool. Laser is placed in a cutting or focused mode held perpendicular to the tissue. A predetermined surgical outline is followed by means of a tissue pickup; a border of the outline is raised and the lesion is then undermined with traction and counter traction would be done with scalpel.
- **Laser peel**—it is usually used to remove the lesion that involves relatively large surface area. Beam is highly defocussed and kept distant from the tissue. Initially, no effect will be seen on the tissue plane Beam is gradually brought closer into focus, but is still in defocussed mode until tissue takes white appearance and begins to blister. Blistering occurs at the basement membrane of the tissue. This whitening technique is extended over the rest of the lesion to be peeled. This white area is then grafted with tissue forceps or hemostat and it is 'laser peeled' away to expose the underlying tissue or vitalization.

- **Ablation**—it is the method of painting away a lesion or tissue removed by laser. It is a non-contact surgical application in which tissue is simply vaporized. It is particularly applied to larger areas of leukoplakia, when surgical excision will create major problems with morbidity and reconstruction. Surface vaporization to a depth of approximately 0.5 mm will normally result in good secondary re-epithelization with normal mucosa. During surface ablation, carbonized layer should be removed before deeper layer is ablated.

Miscellaneous

- **Radiation therapy**—It is utilized only in neoplastic tissue. In some cases, it has been tried, but late observation has failed to show complete success.
- **Topical chemotherapy**—topical application of anticancer chemotherapeutic agent such as bleomycin and human fibroblast interferon have been used with success in limited cases of leukoplakia.

Important Guidelines for Treatment of Leukoplakia (Fig. 12-15)

- Biopsy should be done.
- Leukoplakia that do not heal in 2 to 3 weeks after elimination of demonstrable etiological factors, require conservative and surgical treatment.

Fig. 12-15: Guidelines for the management of leukoplakia in dental office.

- Conservative treatment is applied to a large incipient lesion with keratinization and large verrucous lesions, in order to reduce their size before surgical intervention.
- Surgical treatment is applied if conservative treatment fails to produce complete healing in 3 months at latest.
- Because of higher risk of nodular and verrucous leukoplakia to become malignant, excision of these lesions with adequate follow-up is necessary.
- To prevent malignant changes, all patients reported with leukoplakia are summoned for re-examination at least twice a year.
- Re-biopsy after 5 to 6 months.
- 6 to 10% of leukoplakia with evidence of dysplasia progress to malignancy.
- Recurrence will often follow excision.

Erythroplakia

It is also called as *erythroplasia of Queyrat*, *erythroplasia*. Erythroplakia is a persistent velvety red patch. Reddish color results from absence of surface keratin layer and due to presence of connective tissue papillae containing enlarged capillaries projected close to the surface.

Evolution of the Disease

The first mention of a non-hemorrhagic red patch of an upper aerodigestive tract site was in a vocal cord lesion reported in 1852. The first truly descriptive paper of erythroplakia, however, was a 1911 report by Queyrat, of a red macule on the glans penis of a syphilitic patient. It was Queyrat who coined the term "*erythroplasia*."

About the same time, Rubin used the term "*incipient carcinoma*" to describe the microscopic features of erythroplakia, most common histopathologic diagnosis as carcinoma in situ, based on his experience with lesions of uterine cervix.

Definition

- It is applied to any area of reddened, velvety-textured mucosa that cannot be identified on the basis of clinical and histopathologic examination as being caused by inflammation or any other disease process.
- A chronic red mucosal macule which cannot be given any other specific diagnostic name and cannot be attributed to traumatic, vascular or inflammatory causes.

Classification

- *Homogenous*—these commonly occur on buccal mucosa with well demarcated margin.
- *Erythroleukoplakia*—erythroplakia interspersed with patches of leukoplakia.
- *Granular or speckled*—these are elevated lesions.

Etiology

- *Idiopathic*—in most of the cases cause for erythroplakia is not found.
- *Alcohol and smoking*—these can act as predisposing factors for erythroplakia.
- *Candida infection*—a secondary infection or super infection with candidiasis may be associated with dysplastic oral mucosal cells. *Candida albicans* has often been demonstrated in erythroleukoplakia lesions and the red component of these lesions (often the white component as well) diminishes or disappears after antifungal therapy, in at least some cases.

Clinical Features

- *Age and sex*—male predilection and most common in 6th and 7th decade of life.
- *Sites*—erythroplakia occurs on all mucosal surfaces of the head and neck area. Half of all cases, however, are found on the vermilion or intraoral surfaces, with the rest being evenly divided between the larynx and the pharynx. Vermilion lesions are relatively common and are most often seen on the lower lip. Intraorally, the lateral and ventral tongue, floor of mouth, buccal vestibule and soft palate are most frequently involved.
- *Symptoms*—erythroplakia, as the name obviously implies, is asymptomatic.
- *Appearance*—it is nonelevated, red macule or patch on an epithelial surface. The exact cause of the red appearance is unknown, but may be related to an increase in the number of underlying blood vessels through which the blood flows, which in turn may be secondary to localized inflammatory or immunological responses caused by the dysplastic, i.e. 'foreign,' epithelial cells. In some cases, the color may result from a lack of surface keratin or extreme thinness of the epithelium.
- *Extent*—unlike leukoplakia, erythroplakia is seldom multiple and seldom covers extensive areas of mouth. Also unlike leukoplakia, erythroplakia seems seldom to expand laterally after initial diagnosis, although this may be an artifactual feature because most lesions are completely removed or destroyed immediately after formal diagnosis.
- *Homogenous form*—homogenous form appears as a bright red, soft, velvety lesion with straight or scalloped, well-demarcated margins (**Fig. 12-16**). It is often quite extensive in size. Regardless of the cause of the color change, the typical lesion is less than 1.5 cm in greatest diameter and half are less than 1.0 cm, but lesions larger than 4 cm have also been seen. It usually quite sharply demarcated from the surrounding pink mucosa and its surface is typically smooth and regular in coloration.

Fig. 12-16: Homogenous type of erythroplakia with bright red lesion with well demarcated margin seen in buccal vestibule.

- *Granular or speckled form*—these are soft, red lesions that are slightly elevated with irregular outlines and granular or finely nodular surface speckled with tiny white plaques (**Fig. 12-17**).
- *Smooth erythroplakia* is soft to palpation and has often been described as having a velvety feel. The pebbled lesions tend to be somewhat firm, but erythroplakia never actually becomes hard or indurated, until an invasive carcinoma develops within it.
- *Erythroleukoplakia*—it is quite common to see erythroplakia admixed with or adjacent to leukoplakia in mouth. In such lesions, the red areas are the sites most likely to contain or to develop dysplastic cells and should therefore be the sites most readily biopsied and most carefully examined clinically. Erythroplakia interspersed with patches of leukoplakia in which erythematous areas are irregular and often not as bright as homogenous form, are most frequently seen on tongue and floor of mouth. The borders may be well circumscribed or blend impercibly with surrounding oral mucosa.

Fig. 12-17: Granular form of erythroplakia showing elevated irregular outline (Courtesy Dr Suwas Darvekar).

Diagnosis

- *Clinical diagnosis*—red well demarcated path with no sign of infection and inflammation give rise to diagnosis of erythroplakia.
- *Toluidine blue test*—Differentiation of erythroplakia with malignant changes and early squamous cell carcinoma, from the benign inflammatory lesions of oral mucosa is enhanced by use of 1% toluidine blue test. The solution is applied locally by swab or oral rinse. Malignant type retains it, owing to increased nuclear DNA content of tumor cells.
- *Laboratory diagnosis*—biopsy exhibits epithelial changes ranging from mild dysplasia to carcinoma in situ and even invasive carcinoma.

Differential Diagnosis

- *Candidiasis*—lesion can be rubbed off and it is commonly seen on the tongue.
- *Denture stomatitis*—unusually site is the palate or any denture bearing area.
- *Tuberculosis*—tuberculous ulcers are present which have rolled margins.
- *Histoplasmosis*—it is more common in farmers and present as a single ulcer.
- *Area of mechanical irritation*—cause can be identified.
- *Macular hemangioma*—lesions blanch on pressure.
- *Talangiectasia*—characteristic appearance seen on soft palate.
- *Traumatic lesion*—cause can be identified.

Management

- *Removal of cause*—elimination of a suspected irritant should be carried out.
- *Incisional biopsy*—it is always preferred method for establishing a microscopic diagnosis of suspicious intraoral lesions. Since erythroplakia is so closely correlated with severe dysplasia, carcinoma in situ and invasive carcinoma, incisional biopsy is especially indicated. Excisional biopsy of a potential malignancy may result in under treatment and violation of surgical oncologic principles.
- *Surgical stripping*—the definitive treatment of erythroplastic lesions remains controversial. A conservative surgical procedure such as mucosal stripping is often performed, with minimal damage to the deeper connective tissues. This has the distinct advantage of preserving tissues for microscopic evaluation of potential regions of invasion.
- *Destructive technique*—destructive techniques such as laser ablation, electrocoagulation and cryotherapy have also proved to be effective.

- **Clinical follow-up**—the key to therapy in this disease is extended clinical follow-up. Patients should be examined every 3 months for the first postoperative year and every 6 months for an additional 4 years. After that, annual reevaluation with a thorough head and neck examination is advisable.

Carcinoma in situ

It is also called as '*intraepithelial carcinoma*'. Severe dysplastic changes in a white lesion indicate considerable risk of development of cancer (**Fig. 12-18**). The more severe grade of dysplasia merges with the condition known as carcinoma in situ. It is more common on skin but can also occur on mucous membrane.

Clinical Features

- **Age and sex**—male predilection and occurs more commonly in elderly persons.
- **Sites**—common sites are floor of mouth, tongue and lips.
- **Appearance**—appearance of the lesion may be like leukoplakia and erythroplakia. It may be a combination of leukoplakia and erythroplakia, ulcerated lesion, ulcerated and white lesion, red and ulcerated lesion or may be non-specific.

Diagnosis

- **Clinical diagnosis**—clinically one cannot diagnose carcinoma *in situ*. It may appear like leukoplakia, erythroplakia or both.
- **Laboratory diagnosis**—in biopsy, keratin may or may not be present in/on the surface of lesion; but if present, is more apt to be parakeratin, rather than orthokeratin. Loss of orientation of cells and their polarity (**Fig. 12-18**). Sharp line of division between normal and altered epithelium extending from the surface, down to the connective tissue rather than blending of the epithelium. An increase in nuclear/cytoplasmic ratio and nuclear hyperchromatism are sometimes seen.

Fig. 12-18: Carcinoma *in situ* showing dysplastic changes.

Management

- **Surgical removal**—lesion may be surgically excised, cauterized and even exposed to solid carbon dioxide.

Actinic Keratosis

Actinic keratosis is a cutaneous premalignant lesion. Similarly actinic cheilitis which is associated with lower lip is described in Chapter 23: Diseases of Lip.

Etiology

- **Ultraviolet radiation**—this radiation can produce mutation in p53 suppressor gene. This will cause alteration in skin.

Clinical Features

- **Age and sex distribution**—it is more common in older age group. It is more commonly seen in men.
- **Site**—it is more commonly seen on face, neck, dorsum of hands, the forearms and scalp of bald headed men.
- **Appearance**—they are irregularly scaly plaques. Background is erythematous.
- **Color**—they vary in color from normal white, gray, brown.
- **Size**—the size of lesion is usually less than 7 mm in diameter.
- **Sandpaper texture**—palpation of the lesion shows/feels roughened texture which resembles as sandpaper.
- **Keratin horn**—in some cases, lesion may produce so much keratin that it appears as keratin horn from central area.

Management

- **Cryotherapy**—it is done with the help of liquid nitrogen.
- **Other therapy**—other therapy like topical application of 5-fluorouracil, curettage, electrodesiccation or surgical excision.

Oral Lesions Associated with Use of Tobacco

Stomatitis Nicotina

It is also called as '*smoker's palate*', '*stomatitis nicotina palati*'. It refers to a specific white lesion that develops on the hard and soft palate in heavy cigarette, pipe, and cigar smokers. In many cultures, hand rolled cigarettes and cigars are smoked with the burning end held within the mouth. This habit is called as '*reverse smoking*' and the lesion associated with it is called as '*reverse smoker palate*'. The reason for

occurrence of the lesion is due to heat rather than an effect of tobacco (**Fig. 12-19**).

Fig. 12-19: Well defined reddened area seen in palate of patient who is having habit of reverse chutta smoking (Courtesy Dr Chole).

Types (Clinical)

- *Mild*—consisting of red, dot like opening on blanched area.
- *Moderate*—characterized by well defined elevation with central umbilication.
- *Severe*—marked by papules of 5 mm or more with umbilication of 2-3 mm.

Palatal Change in Reverse Smoking

- *Keratosis*—diffuse whitening of the entire palatal mucosa.
- *Excrescences*—1-3 mm elevated nodules, often with central red dots corresponding to the opening of palatal mucous glands.
- *Patches*—well defined, elevated white plaques, which could qualify for the clinical term leukoplakia.
- *Red areas*—well defined reddening of the palatal mucosa.
- *Ulcerated area*—crater-like areas covered by fibrin.
- *Non-pigmented areas*—area of palatal mucosa which is devoid of pigmentation.

Clinical Feature

- *Age and sex distribution*—it is usually seen in men who are pipe smokers. It is common in middle age and elderly adults.
- *Site*—most commonly affected site is palate. The lesion is well developed and prominent on keratinized hard palate. It is restricted to the area which is exposed to heavy cigarette smoke.

- *Onset*—initially there is redness and inflammation of the palate.
- *Appearance*—In the early stages, mucosa is reddened. It subsequently becomes grayish white (**Fig. 12-20**), thickened and fissured. Fissures and cracks may appear producing a wrinkled, irregular surface. In some cases, there may be papular or multinodular appearance. Papules do not coalesce and are separated from one another by intervening normal appearing mucosa. Tonsillar pillars are usually erythematous.

Fig. 12-20: Grayish white appearance of palate seen in smoker's palate.

- *Dried mud appearance*—in some cases, palatal keratin becomes so thickened that it impart fissure or dried mud appearance (**Fig. 12-21**).

Fig. 12-21: Dried mud appearance seen in stomatitis nicotina.

- *Salivary gland opening*—discoloration is homogenous with the exceptions of numerous erythematous spot (**Fig. 12-22**). It represent focal thickening surrounding the orifice of the salivary gland which appears as white umbilicated nodule with red center that may be stain brown by deposit of tar.

Fig. 12-22: Salivary gland opening seen as numerous erythematous spots in palate.

Diagnosis

- *Clinical diagnosis*—history of cigar or pipe smoking and reverse smoking with generalized lesion of palate is key for the diagnosis of stomatitis nicotina.
- *Laboratory diagnosis*—in biopsy epithelium shows acanthosis and hyperkeratosis. Epithelium lining of minor salivary gland often shows squamous cell metaplasia and hyperplasia.

Differential Diagnosis

- *Papillary hyperplasia*—the lesion displays cobblestone appearance and in stomatitis nicotina, there is red center located on the palate of pipe or cigar smokers. The papules of the papillary hyperplasia are focal.
- *Darier's disease*—they appear diffusely on palate in cobblestone pattern.
- *Focal epithelial hyperplasia*—it is not common on palate and they are not erythematous.
- *Cowden syndrome*—these are multiple papillary nodules commonly seen on gingiva.

Management

- *Stoppage of habit*—it is completely reversible, once the habit is discontinued. The lesions usually resolve within 2 weeks of cessation of smoking.
- *Biopsy*—biopsy of nicotine stomatitis is rarely indicated. But biopsy should be performed on any white lesion of the palatal mucosa that persists after 1 month of discontinuation of smoking habit.

Snuff Dipper Lesion

It is also called as *snuff pouch*, *tobacco pouch keratosis*, *spit tobacco keratosis*, *smokeless tobacco keratosis*. The habit of chewing tobacco is called as *smokeless tobacco* or *spit tobacco* use.

Etiopathogenesis

- *Nicotine*—the compound N-nitroso-nor-nicotine (NNN), which is derived partly from bacterial action on nicotine during the curing process, is contributed by the action of salivary nitrites, when tobacco is held in the mouth; occurs in greater concentration in snuff tobacco.

Clinical Features

- *Location*—it occurs in mucosal surface, where snuff is habitually held.
- *Gingiva and periodontal tissue*—there is painless loss of gingival and periodontal tissue in the area of tobacco contact.
- *Teeth*—there is extrinsic stain present on the teeth. There is also cervical erosion of teeth with more prevalence of dental caries.
- *Smokeless tobacco keratosis*—it is white plaque present in the mucosa where chewing tobacco is kept. It is thin, gray or gray-white translucent lesion (Fig. 12-23). Margin of the lesion blends gradually into surrounding mucosa.

Fig. 12-23: Grayish lesion seen in buccal vestibule of patient where he uses to keep tobacco.

The appearance of lesion depends upon hours of daily use and use of different tobacco leaves.

- *Snuff pouch, tobacco pouch*—mucosa is soft velvety touch feel on palpation and stretching of mucosa reveal distinct 'pouch'. Stretched mucosa appears fissured and ripped in sand on a beach after an ebbing tide.
- *Malignant transformation*—verruccous carcinoma has been reported to occur from snuff dipper lesion. This is also called as snuff dipper cancer.

Management

- *Stoppage of habit*—maximum lesion is regress following the caseation of habit.
- *Biopsy*—any lesion which remains after 6 months quitting the habit should be send for biopsy.

Cigarette Smoker's Lip Lesion

They are generally flat or slightly elevated nodular white lesion on one or both lips, corresponding to the site at which the cigarette is held and apparently smoked down to an extremely short length.

There is increased redness and stippling of lip in localized area. Margin has elliptical, circular or irregular borders. Color is pale to white (Figs 12-24A and B) and is slightly elevated with nodular or papillary shape.

Pre-malignant Conditions

Lichen Planus

Erasmus Wilson described it in 1869. The term lichen planus is derived as lesion they look like lichen on the rock and planus is for flat. Various mucosal surfaces may be involved, either independently or concurrently, with cutaneous involvement or serially. Oral mucosa is frequently involved. It is a probable pre-cancerous condition. Lichen planus is a common inflammatory disease of the skin presenting with characteristic violaceous, polygonal, pruritic papules. The disease may also affect the mucosa, hair and nails.

It is relatively common dermatological disorder occurring on skin and oral mucous membrane and refers to lace-like pattern produced by symbiotic algae and fungal colonies on the surface of rocks in nature (lichens).

Prevalence of lichen planus in general population is about 0.9% to 1.2% and prevalence of oral lichen planus is reported between 0.1% and 2.2%.

Etiology

- *Cell mediated immune response*—it is a cell mediated immune response associated with lymphocyte-epidermal interactions, resulting in degeneration of basal cell layer. This occurs due to alternation of

Fig. 12-24: Cigarette smoker's lip lesion. (A) Lesion on the lower lip. (B) Lesion on the lower lip.

keratinocytes as a result of unknown events resulting in antigenic alternation of these cells thereby stimulating immunological reaction. Another hypothesis is that it is a primary immunologic reaction causing alternation and degeneration of keratinocytes. Cell mediated immune response may be caused by various mononuclear cells i.e. langerhans cell, macrophages predominantly T lymphocytes, lymphoblast cells, B lymphocytes and mast cells. These cells infiltrate the upper part of lamina propria of submucosa. The macrophages are mostly mature, which probably have functional role with mononuclear cells suggesting of cell-to-cell co-operation.

- *Recent hypothesis of pathogenesis of lichen planus.* In a genetically predisposed individual, haptens (certain drug or dental material), conventional antigen or super-antigen of oral microbial origin can induce cell mediated immune response resulting in sub-epithelial T cell infiltration of the site in oral mucosa with cytokine generation HSP-60 and C 1/10 expression by basal keratinocytes. If individual is not predisposed to react to HSP-60, then non-specific mucositis occur. If the

individual has genetic predisposition, it results in autoimmune reaction → activation of cytotoxic T cell → destruction of basal keratinocytes → oral lichen planus.

- *Auto-immunity*—the activated T lymphocytes also secrete gamma interferons which induce keratinocytes to produce HLA-DR and increase their rate of differentiation with formation of thickened surface. Antigenic information is transferred from 'Langerhans' cells to lymphocytes, when there is mutual expression of HLA-DR. Lymphocytes normally are attracted towards HLA-DR expressing keratinocytes and may contact the epithelial cell. During this contact, inappropriate epithelial antigenic information may be passed to lymphocytes due to HLA-DR linkage. With this mechanism, self antigen may be recognized as foreign bodies, leading to destruction of basal cells, resulting in an autoimmune response. There are numerous studies which show immune deposits in lichen planus affected tissues but it is not specific.
- *Immunodeficiency*—there has been report of decreased serum levels of IgG, IgA, or IgM in lichen planus and the possibility of it as a manifestation of immunodeficiency has been raised. But at the same time, reports of normal concentrations of IgA and IgM are found; therefore the role of immunodeficiency is questionable.
- *Genetic factors*—cases of lichen planus are reported in families, twins and husband and wife. Clinically, familial lichen planus is somewhat unusual as it appears to affect young patients, is severe, often extensive, involves skin, nails and mucous membrane and is persistent. It has also been suggested that familial cause might be environmental and related to infection, rather than to genetics.
- *Infection*—a bacterial etiology may be there but results are not confirmed. Spirochetes and rod-like bodies resembling bacteria have also been detected.
- *Psychogenic factor*—a relationship of lichen planus with stress is quoted and neurogenic basis is suggested. Observation mostly in nervous and highly stressed persons is associated with emotional upset, over work and some form of mental strain.
- *Habits*—oral lichen planus have shown association with tobacco habit. Chewers of tobacco and betel have increased prevalence of oral lichen planus. Smoking may play a role in initiating oral lichen planus of plaque type.
- *Miscellaneous*—occurrence of lichen planus is also suggested in association with deficiency of vitamin B₁, B₆ and C, electric potential difference, anemia and patients with secondary syphilis. It can also occur in some cases due to trauma and malnutrition. Exacerbation of lichen planus also correspond to periods of emotional upset, overwork, anxiety, hysteria attack, depression and some form of mental strain.

Types

- Reticular
- Papular
- Plaque
- Atrophic
- Classical
- Erythematous
- Ulcerative
- Hypertrophic
- Erosive
- Bullous
- Hypertrophied
- Annular
- Actinic
- Follicular
- Linear

Clinical Features

- *Age and sex*—it occurs in adulthood with age range for males as 35-44 years and for females 45-54 years. It has more predilections for females.
- *Site*—it may involve skin, oral and other mucous membranes. About 50% of the patients with skin lesions have oral lesions whereas 25% of all lichen planus have only oral lesions. Other mucosal surfaces including larynx, glans penis, esophagus, stomach, nasal and vulva may get involved.
- *Symptoms*—the chief complaint is usually of intense pruritus. The itching associated with LP usually provokes rubbing of the lesions, rather than scratching.
- *Signs*—the lesions have a characteristic violet hue. They are flat-topped, shiny, polygonal papules and plaques. The surface is dry with thin, adherent scales (**Fig. 12-25**).

Fig. 12-25: Lichen Planus seen on the hand of the patient.

- *Six P* of lichen planus—six 'p's characterize the lesions LP: they are planar, polygonal, purple, pruritic, papules and plaques.
- *Vaginogingival syndrome*—oral lesions coexisting with genital mucosal lesions are known as *vaginogingival syndrome*.
- *Skin lesion*—skin lesions appear as small, angular, flat topped papules, only a few mm in diameter, which may be discrete or gradually coalesce into larger plaque and is covered by fine glistening scales (**Fig. 12-26**).

Fig. 12-26: Lichen Planus seen on hand of patient. It is showing glistening scale (Courtesy Dr Chole).

- **Color**—papules are sharply demarcated from surrounding skin, which appears red but soon takes reddish purple or violaceous blue color. Later, dirty brown color develops. Center of papule may be slightly umbilicated
- **Wickham's striae**—these are very fine grayish lines which cover the papules.
- **Koebner phenomenon**—fresh lesions may appear on scratch marks or at sites of other non-specific trauma.
- **Graham little syndrome**—alopecia occurs in some patients which may be termed lichen planus planopilaris (Graham-Little syndrome). Nail changes, particularly longitudinal ridging and grooving may be seen.
- **Grinspan syndrome**—lichen planus can be associated with Grinspan syndrome which consists of lichen planus, diabetes mellitus and vascular hypertension.
- **Complication**—it includes post-inflammatory hyperpigmentation, malignancy from oral lesions, nail dystrophy and scarring alopecia.

Oral Lichen Planus

- **Sites**—common sites are buccal mucosa (84%) and to lesser extent tongue, lips, gingiva, floor of mouth (Fig. 12-27) and palate.
- **Symptoms**—patient may report with burning sensation of oral mucosa.
- **Appearance**—oral lesion is characterized by radiating white and gray velvety thread-like papules in a linear, angular or retiform arrangement forming typical lacy, reticular patterns, rings and streaks over the buccal mucosa and to a lesser extent on the lip, tongue and palate.
- **Wickham's striae**—tiny white elevated dots are present at the intersection of white lines, called as Wickham's striae.
- **Superimposed candidial infection**—in some cases superimposed candidial infection may present.

Fig. 12-27: Lichen Planus seen in floor of mouth showing radiating striae.

- **Reticular type**—it is most common form and is mostly bilateral. It consists of slightly elevated fine whitish lines that produce lace-like pattern of fine radiating lines, called as Wickham's striae (Figs 12-28A to C). The lesion may present radiating white thread like papules in a linear, annular or retiform arrangement. A tiny white dot is frequently present at the intersection of white lines.

Fig. 12-28A

Fig. 12-28B

Fig. 12-28C

Figs 12-28A to C: Reticular type of Lichen Planus seen on buccal mucosa.

- *Papular*—whitish elevated lesions of 0.5 mm to 1 mm in size, well seen on keratinized areas of oral mucosa. Papules are spaced apart; still close enough to give pebbled white or gray color (**Fig. 12-29**). Sometimes they coalesce. Most often, papules are seen at the periphery of reticular pattern.

Fig. 12-29: Papular type of Lichen Planus seen on lip.

- *Plaque*—it is seen on dorsum of tongue and buccal mucosa. In case of plaque of tongue, disappearance of the tongue papillae is seen. It spreads in concentric peripheral growth. It consists of either pearly white or grayish white plaque. Such plaques generally range from slightly elevated and smooth to slightly irregular form (**Fig. 12-30**).
- *Atrophic form*—it appears as smooth, red, poorly defined area, often but not always, with peripheral striae evident. The attached gingiva is frequently involved in this form of lichen planus is called desquamative gingivitis pattern (**Fig. 12-31**). At the margins of atrophic zones,

Fig. 12-30: Plaque type of Lichen Planus showing slightly elevated lesion.

whitish keratotic striae are usually evident, radiating peripherally and blending into surrounding mucosa. The gingiva tends to show patchy distribution over all the four quadrants in a relatively symmetrical pattern. It is always symptomatic with complain of pain and burning in the areas of involvement.

Fig. 12-31: Atrophic form of Lichen Planus showing involvement of attached gingiva.

- *Bullous form*—it consists of vesicles and bullae which are short lived. These upon rupturing, leave an ulcerated extremely uncomfortable surface (**Fig. 12-32**). The most common site is buccal mucosa especially into posterior and lateral margins of tongue. It is often associated with striated or keratotic component.
- *Hypertrophic form*—it appears as well circumscribed, elevated white lesion resembling leukoplakia.
- *Annular form*—it appears as round or ovoid, white outline with either pink or reddish pink center.

Fig. 12-32: Bullous form of Lichen Planus showing ulceration in posterior area.

- *Pigmented lichen planus*—in many cases, lichen planus is associated with pigmentation (**Fig. 12-33**).

Fig. 12-33: Lichen Planus associated with pigmentation in on buccal mucosa.

- *Malignant potential*—the incidence of malignant transformation ranges from 0.4% to 12.3%. In India, the incidence of malignant transformation is 0.4%. Carcinoma development is more common in women than in men. Atrophic, erosive and ulcerative lesions showing erythroplakic component and tobacco chewers are indicated to be more cancer prone.

Clinical Variation of Lichen Planus

In many cases, the clinical picture may differ from the classical one, the variations being in morphology and configuration or there may be modifications of clinical features by the site of involvement.

Variations in morphology

- *Hypertrophic lichen planus*—this may occur as a sole manifestation or as a part of a more generalized subacute disease. The lesions are elevated, warty, pigmented plaques typically occurring on the shin or around the ankle. These lesions tend to be persistent.
- *Atrophic lichen planus*—the lesions are few in number. There are depressed, pigmented lesions.
- *Follicular lichen planus*—it is also known as *lichen planopilaris*, this may accompany typical lesions or may be the sole morphologic type. There are small lesions centered on hair follicles. Lesions on scalp may result in alopecia. The combination of follicular LP with scarring alopecia of scalp and non-scarring alopecia of axilla and pubis or other areas is known as *Graham-Little syndrome*.
- *Actinic lichen planus*—described mainly from the Middle East and India, these lesions are common on the face and present as hyperpigmented patches with a surrounding zone of hypopigmentation.
- *Bullous lichen planus*—vesicles and bullae may occur on typical lesions of LP in this variant, due to severe basal cell degeneration induced by the inflammatory process.
- *Ulcerative lichen planus*—chronic ulcers occur on the feet. It may accompany oral ulcer and loss of nails.
- *Lichen planus pigmentosus*—described mainly from India and Middle East, these lesions present with deeply pigmented macules on the face and extremities.

Variations in shape:

- *Linear lichen planus*—this may follow marks of injury by koebnerization, or may occur spontaneously in long linear arrays or rarely in a dermatome in a zoster-like fashion.
- *Annular lichen planus*—these lesions have central depressed areas with raised margins. Typically occurs on penis.
- *Guttate lichen planus*—large number of drop-shaped lesions.

Variation by site

- *Oral*—oral lesions frequently occur in lichen planus.
- *Genital*—annular plaques often occur on glans penis, vulval or vaginal lesions, often presenting with chronic ulcers, may rarely occur.
- *Nails*—nail dystrophies may occur in lichen planus. The various changes that may occur are: thinning of nail plate, longitudinal ridging, onycholysis, subungual hyperkeratosis and pterygium formation (fusion of proximal nail fold with the nail plate).
- *Palms and soles*—lichen planus of these locations lack the typical color; they are yellowish rather than violaceous papules and plaques.

- *Scalp*—follicular lesions with scarring alopecia are seen at this site.

Special variant

- *Drug-induced lichenoid reactions*—a number of drugs may induce development of lesions that clinically and histologically resemble idiopathic lichen planus. The principal offenders are: gold, penicillamine, beta-blockers, anti-malarials, captopril, lithium, carbamazepine, chlorpromazine, thiazides, methyldopa, and NSAIDs.
- *Lichen planus pemphigoides*—bullous lesions occur on lesions as well as normal skin. This appears to be a variant with combined features of lichen planus and bullous pemphigoid.
- *Lichenoid contact dermatitis*—contact with color film developer containing paraphenyldiamine may give rise to lichen planus like lesions on hands. Amalgams in dental filling material may also give rise to lichenoid oral lesions.
- *Lichen planus-lupus erythematosus overlap*—lesions with atrophic center violaceous border occur mainly on hands and feet. Immunohistologic evidence of both lichen planus and lupus erythematosus, are present.

Diagnosis

- *Clinical diagnosis*—the interlacing white striae appearing bilaterally. Presence of Wickham striae and Koebner phenomenon is also diagnostic.
- *Laboratory diagnosis*—there is hyperorthokeratosis, hyperparakeratosis, acanthosis with intercellular edema of spinous cells. Biopsy also shows *civatte bodies* in spinous and basal cell layers and lamina propria. *Saw tooth appearance* of the rete pegs is seen.
- *Immunofluorescent study*—positive for direct immunofluorescence reaction with IgA, IgM, IgG antisera. Most constant feature is presence of sub-epithelial deposits of fibrinogen and antigenically related substance, which can be stain by anti-fibrinogen antisera.

Differential Diagnosis

- *Leukoplakia*—men are more commonly affected as compared to lichen planus. Also in lichen planus, Wickham's striae are present.
- *Candidiasis*—pseudomembrane can be rubbed off in case of candidiasis.
- *Pemphigus*—characteristic clinical white striation of lichen planus are usually evident in cases. Diagnosis of pemphigus can be made by microscopic finding of acantholysis.
- *Lupus erythematosus*—Not in fine reticular pattern, but have much broader dimension. Flaky and feathery appearance of lupus lesion.

- *Drug induced lesion*—history of drug administration.
- *White sponge nevus*—it is seen at birth and puberty; lichen planus is seen over the age of 30 years.
- *Ectopic geographic tongue*—red center with slightly raised margins which rapidly alter.
- *Cheek biting*—history of trauma is usually given.
- *Lichenoid drug reaction*—initiate a course of systemic administration of steroids, if no improvement occurs in 2 weeks, lichenoid reaction will be the working diagnosis.

Management

- *Removal of cause*—the causative factor is removed and this may lead to resolution of lesion subsequently. This can be particularly applicable to lichenoid drug eruption.
- *Steroids*—in most patients with erosive and ulcerative lesion steroids are commonly used. The rationale behind their use is their ability to modulate inflammation and immune response. Topical and intralesional routes are used when systemic steroids are contraindicated. These routes are useful when the patient refuses needle injection or when treating painful gingival sites, where injection delivery is impossible. The topical, injectable and systemic routes are used when there is no systemic contraindication and a full steroid dose is required.
- *Steroid spray*—small and moderately sized painful lesions can be treated with *beclomethasone dipropionate spray*, *triamcinolone acetonide* in gel or cream base.
- *Steroid coating in soft custom tray*—in case of some painful gingival lesions topical steroids may be applied using soft custom trays by coating steroids on the undersurface of the tray. This tray anchors to the dental arch while covering the painful gingival lesion.
- *Topical delivery regimen*—this earlier regime called topical delivery QID, for 3 or more weeks, once a week intralesional injection, for 3 weeks (usually -0.5 ml – 1.5 ml) and systemic steroid (prednisolone 5 mg tab) in tapering doses of 30 mg/day for the first of 3 weeks, 15 mg/day for second week and 5 mg/day for third and final week. Intralesional injections which are used are *methylprednisolone* 40 mg/ml and *triamcinolone acetonide* 10 mg/ml.
- *Topical application*—topical application of *fluocinolone acetonide* for 4 weeks is also effective in curing the disease (**Fig. 12-34**).
- *Combination of prednisolone and levamisole*—another regime consisting of prednisolone and levamisole has also been tried successfully recently. This systemic regime calls for prednisolone 5 mg and levamisole 50 mg tablets for first three days of rest and this schedule to be followed for two to three more weeks.

Fig. 12-34: Post-treatment photograph of Lichen Planus (Courtesy Dr Tapasya Karamore).

- **Topical application of antifungal agent**—it is given when candidiasis superimposed lichen planus. Steroid therapy is routinely accompanied by antifungal treatment as steroid therapy tends to generate an oral fungal infection. The prophylactic antifungal therapy usually consists of clotrimazole oral torches. Nystatin and ketoconazole can also be used.
- **Vitamin A (retinoid) analogue**—retinoids are useful usually in conjunction with topical corticosteroids as adjunctive therapy either topically or systemically. This is because of their anti-keratinizing and immunomodulating effects. They are particularly effective against keratinized reticular and plaque variants.
 - **Topical vitamin A acid cream (0.1%)** Tretinoin, beta altransretinoic acid, systemic etretinate and systemic and topical isotretinoin are also useful in resolution of the lesions, but withdrawal of the medication leads to rapid recurrence to the lesion very oftenly.
 - **Side effect**—the side effects of retinoids are more and it includes foci of erythema during and after the topical treatment. For systemic retinoids, it includes liver dysfunction, cheilitis and dryness of mucous membrane.
 - **Temarotene**—a new systemic retinoid; temarotene, has been reported effective and free of side effects, other than a slight increase in liver enzymes.
- **Cyclosporine**—it is a selective inhibitor of CD₄ helper T lymphocytes that is used systemically to achieve immunosuppression. It can be used both, topically and systemically. The lesion shows complete healing with no recurrence following 8 weeks of systemic cyclosporine 8 mg/kg/day. Oral lesions can be treated using cyclosporine as a rinse and expectorant. It is used as 5 ml rinse, TID, for 8 weeks.

- **Surgical therapy**—it is indicated when conventional methods fail in ulcerative lesion and small solitary lesions. In some cases, cryosurgery and cauterization have also been tried.
- **Psychotherapy**—emotional status of the patient is important in the development of this disease. In some cases, the lesion may regress when the patient is made aware of psychogenic implication of the condition and the nature of emotional stress is understood. When the lesions are asymptomatic and there is no source of emotional distress, it is often advisable to refrain from therapy as failure to eradicate the lesion by medication may trigger the patient into becoming fearful of cancer. Tranquilizers have also been tried to reduce anxiety.
- **Dapsone therapy**—dapsone diamino-diphenylsulphone is an antibacterial sulphone. It is postulated that this particular agent may help to control the lymphocyte mediated progress of lichen planus by modulating the release of inflammatory or chemotactic factor for mast cells or neutrophils. It is used in severe form of erosive lesions.
- **PUVA therapy**—In this form of therapy, psoralens and high intensity long wave ultraviolet A (PUVA) light is used as a therapeutic agent. The lesion shows improvement during and immediately after the treatment.
- **Fluocinonide**—fluocinonide in an adhesive base can be useful in treating lichen planus.
- **Symptomatic**—it can be provided by topical analgesic, topical anesthetic and anti-histaminic rinse.
- **Others**—apart from above mentioned therapies various other agents are also used in treatment of lichen planus. It includes vitamin B complex, heavy metal preparation such as those containing bismuth, arsenic and mercury, antibiotics such as penicillin, doxycycline, radiation, chloroquine therapy and immunization therapy.

Table 12-1: Treatment options

Group	Treatment
Group I—Lichen Planus of reticular or atrophic variety without symptoms	• No treatment is required • Regular follow-up • Diazepam for anxiety
Group II—Lichen Planus of reticular or atrophic variety except with mild to moderate pain and burning	• Local application of benzocaine 10% for burning • 2 mg of diazepam • Topical corticosteroid • Intralesional steroid for quicker relief • Regular follow-up
Group III—erosive Lichen Planus with or without symptoms	• Immediate biopsy • Local control of pain • Intralesional steroid • If infected, antibiotic
Group IV—lichenoid reaction	• Discontinue the offending drug • Local application of benzocaine

Erosive Lichen Planus

It presents as chronic multiple oral mucosal ulcers, which occur when there is extensive degeneration of basal cell layer of epithelium.

Etiology

- *Drug therapy* like NSAIDs, hydrochlorothiazide, penicillamine, angiotensin converting enzyme inhibitors.
- *Chronic hepatitis*—underlying medical disorders like chronic hepatitis.
- *Dental restoration*—reaction to dental restorations.
- *Graft versus host disease*—graft versus host disease due to bone marrow transplantation.
- *Stress*—emotional stress can lead to erosive lichen planus.

Clinical Features

- *Age and sex*—female to male ratio is 2:1. Average age is 50 years. It is primarily a disease of whites, but may be seen in blacks.
- *Sites*—common site is buccal mucosa and lingual mucosa.
- *Symptoms*—patient complains of burning sensation and pain.
- *Appearance*—after rupture of vesicles, eroded or frankly ulcerated lesion are seen which appears as a raw painful areas (Fig. 12-35). Lacy white pattern may be present.
- *Size and shape*—eroded and frankly ulcerated lesions are irregular in size and shape and appear as raw and painful areas (Fig. 12-36).
- *Surface*—the surface is generally granular and brightly erythematous and may bleed upon slight provocation or manipulation.
- *Signs*—a fibrinous plaque or pseudomembrane may be seen over erosion, while later is significant.
- *Malignant potential*—malignant potential is 1 to 25%.

Fig. 12-35: Ulcerated area seen on buccal mucosa in erosive Lichen Planus.

- *Healing*—present for a week to month and heal in periods of 10 days to 2 weeks.

Fig. 12-36: Irregular shaped ulcerated lesion with lacy white pattern at the periphery is seen in erosive Lichen Planus.

Diagnosis

- *Clinical diagnosis*—ulcerative lesion with white lacy pattern is diagnostic indicator of erosive lichen planus.
- *Laboratory diagnosis*—In the erosive form, the epithelium is completely missing or only remnants of epithelial tissues are seen. It shows classical feature of lichen planus, i.e. hydropic degeneration of basal cell layer with juxtaepithelial inflammatory cell infiltrate.

Differential Diagnosis

- *Speckled leukoplakia*—surface is speckled, as compared to erosive lichen planus where it is granular.
- *Squamous cell carcinoma*—borders of the lesion are ill defined and surface is irregular.
- *Lichenoid drug reaction*—history of drug administration.
- *Electrogalvanic mucosal lesion*—dissimilar restorations present in the oral cavity.
- *Psoriasis*—Auspitz's sign is positive.
- *Atrophic candidiasis with keratotic borders*—can be confused with an erosive lichen planus especially when the candidial focus is circumscribed by a keratotic border; proof of cause is searched for typical lichen planus.
- *Cicatricial pemphigoid*—eye lesions are present in cases of cicatricial pemphigoid.
- *Erythema multiforme*—onset less acute, whitish lichen design on the borders of erosion and skin changes occur in case of lichen planus.
- *Desquamative gingivitis*—the gingival surface is smooth and shiny and there is patchy distribution of red and gray areas.
- *Bullous skin lesion*—lichen planus lesion yields a negative blister induction test.

- *Recurrent aphthae*—whitish changes in border lesion present in case of lichen planus, which is absent in the case of recurrent aphthae.
- *Primary syphilitic lesion*—painless indurated edema, painless swollen lymph nodes.

Management

It is same which is given for other type of lichen planus.

Graft-versus-Host Disease (GVHD)

It occurs in a person who receives allogenic bone marrow transplantation. This occurs when in some cases in spite of HLA matching donor person rejects allogenic bone marrow transplantation and patient can suffer from variety of signs and symptoms.

Clinical Features

- *Acute GVHD*—it is seen after one or two weeks of allogenic bone marrow transplantation. The skin lesion ranges from mild rash to diffuse severe sloughing. It is also associated with diarrhea, nausea, vomiting, abdominal pain, liver dysfunction.
- *Chronic GVHD*—it may develop after 3 months of duration. Skin lesion resembles as lichen planus. Some patients may notice features similar to lupus erythematosus, Sjögren syndrome.

Oral Manifestation

- *Site*—tongue, labial mucosa, and buccal mucosa are most commonly involved site.
- *Symptoms*—burning sensation and mucosal discomfort is present. Patient also complains of xerostomia.
- *Lichen planus like lesion*—oral lesion of graft versus host resistance resembles lichen planus (Fig. 12-37).

Fig. 12-37: Lichen Planus type lesion seen in patient with allogenic bone marrow transplantation.

- *Sign*—in some cases patient may notice mucocele showing signs of salivary gland involvement.

Diagnosis

- *Clinical diagnosis*—lichen planus type of lesion with history of allogenic bone marrow transplantation will diagnose this condition.
- *Laboratory diagnosis*—there is abnormal deposition of collagen. Other features are similar to lichen planus.

Management

- *Topical steroids*—topical steroids will facilitate healing of oral ulceration.
- *Topical anesthetics gel*—it is also used to control burning sensation of oral cavity.
- *Thalidomide*—this is useful drug in cases of chronic GVHD which are resistant to standard therapy.
- *Prevention*—prophylactic therapy with immunomodulator and immunosuppressive drugs such as cyclosporine and prednisone should be given to prevent GVHD. Doses the above drugs should be increased if GVHD occurs.

Lichenoid Reaction

The unifying feature of lichenoid reaction and lichen planus is the similar clinical and light microscopic appearance of the skin and mucous membrane lesions. Lichenoid reactions were differentiated from lichen planus on the basis of association of lichenoid reaction with administration of a drug or a systemic disease and their resolution, when the drug was discontinued.

Etiopathogenesis

- *Disorders*—lichen planus, lupus erythematosus, erythema multiforme, fixed drug eruptions, secondary syphilis and graft-versus-host reaction.
- *Drugs and chemical*—the tissues of a person with diathesis react in a special way to certain extrinsic stimuli, making it more susceptible to certain diseases. Drugs act to increase temporarily the specific antigenic stimulus and hence increase the reaction. If the drug is withdrawn at a later time, the antigenic stimulus is reduced, followed by reduction in clinical severity. It is suggested that drugs that are known to induce lichenoid response, act as agents who amplify the disorder, rather than induce it. To implicate a drug responsible for a lichenoid reaction can be difficult as there is no specific test for it. Association between dental filling material and lichen planus has also been suggested. Following drugs can cause lichenoid reaction.

- *Antimicrobial*—dapsons, para-aminosalicylate, streptomycin and tetracycline.
- *Anti-parasitic*—antimony compounds, organic arsenical, chloroquine and quinacrine.
- *Anti-hypertensive*—chlorothiazide, hydrochlorothiazide, labetalol, mercurial diuretic, methyl dopa and practolol. Angiotensin converting enzyme inhibitors can also cause lichenoid reaction.
- *Anti-arthritis*—aurothioglucose, colloidal gold, gold sodium thiomalate and gold sodium thiosulfate.
- *Oral hypoglycemic agents of sulfonylurea type*—chlorpropamide and tolbutamide.
- *Miscellaneous drugs*—iodides, penicillamine, quinine sulfate and copper in dental casting alloy.

Clinical Features

- *Lichenoid mucositis*—this is a term used for lesion of mucosa similar to lichen planus due to drugs.
- *Lichenoid dermatitis*—when lesion presents on the skin it is called as lichenoid dermatitis (**Figs 12-38A and B**).
- *Lichenoid foreign body gingivitis*—this occurs due to foreign material embedded in gingiva causing host response.

Figs 12-38A and B: Lichenoid dermatitis seen on hand of the patient (Courtesy Dr Pincha).

Diagnosis

- *Clinical diagnosis*—lichen planus type lesion with drug history will diagnose lichenoid reaction
- *Laboratory diagnosis*—lichenoid drug reaction may show deep as well as superficial dermal lymphocyte infiltrates rather than the classical band-like infiltrate of the lichen planus.

Management

Majority of it are resolved after discontinuation of drug.

Oral Submucous Fibrosis (OSMF)

It is a chronic and high risk precancerous condition. The condition was prevalent in the days of Sushruta (600 B.C.), a great practitioner of ancient medicine where he labeled this condition as 'Vidhari'. After lapse of many years, Schwartz (1952) was the first person to bring this condition again into limelight. He described the condition as '*atrophica idiopathica mucosae oris*'. After that, the condition has also been described as idiopathic scleroderma of mouth, idiopathic palatal fibrosis and sclerosing stomatitis.

Definition

- An insidious, chronic disease affecting any part of the oral cavity and sometimes pharynx. Although occasionally preceded by and/or associated with vesicle formation, it is always associated with juxtaepithelial inflammatory reaction followed by fibroelastic changes of lamina propria, with epithelial atrophy leading to stiffness of oral mucosa and causing trismus and inability to eat.

Epidemiology

The disease is very common in India, Indian subcontinent and other Asian people. The prevalence rate of oral submucous fibrosis in India, Burma and South Africa ranges from 0 to 1.2%. In India, overall incidence is about 0.2% to 0.5%. Its incidence is high in southern parts of India, where the incidence of oral cancer is also high.

Etiopathogenesis

- *Chillies*—the use of chillies (*capsicum annum* and *capsicum frutescence*) have been thought to play an etiological role in oral submucous fibrosis. Capsaicin is the active ingredient of chillies. It is the vanillylamide of 8-methyl-6-nonenic acid, which is the active irritant of the chillies.
- *Tobacco*—it is a known irritant and causative factor in oral malignancy. It may act as a local irritant in oral submucous fibrosis.

- *Lime*—lime is used with betel nut for chewing. It causes local irritation and damage to the mucosa with vesicle and ulcer formation in susceptible individuals. It acts as a local irritant.
- *Betel nut*—the term areca nut is used to denote the unhusked whole fruit of the areca nut tree and term betel nut is used exclusively to refer to the inner karnel or seed which is obtained after removing husk. The betel nut has psychotropic and antihelmintic property due to presence of areca alkaloids, predominantly arecoline. These alkaloids have powerful parasympathetic properties which produce euphoria and counteract fatigue. Areca nut is found to contain different types of alkaloids like arecoline, arecadine, arecalidine, guvacoine, guvacine and isoguvacine. The pathogenesis of oral submucous fibrosis caused by betel nut is as follows:
 - *Tannic acid and arecoline content*—in a habitual betel nut chewer, oral submucous fibrosis may be caused by the amount of tannic acid contained in the betel nut, the influence of mixed calcium powder and the conditional action of arecoline content in betel nut, affecting the vascular supply of oral mucosa and causing neurotropic disorder.
 - *Formation of areca nut specific nitrosamine*—nitrosation of arecoline leads to the formation of areca nut specific nitrosamine namely nitrosoguvacoline, nitrosoguvacine and 3-methyl nitrosomino piperidine, which alkylate DNA
 - *Metabolism of areca nut specific nitrosamine*—metabolism of these areca nut specific nitrosamine will lead to formation of cyanoethyl, which adducts with o'-methyl guanine in DNA. Prolonged exposure to this irritant leads to malignant transformation.
 - *Dual action of areca nut*—recently suggested that pathogenesis of oral submucous fibrosis is by dual action of areca nut. It is suggested that arecoline stimulates fibroblastic proliferation and collagen synthesis. The flavanoid catechin and tannins are also components of areca nut and they stabilize the collagen fibrils rendering them resistance to degradation by collagenase. The attendant trismus is the result of juxtaepithelial hyalinization and secondary muscle involvement. Glycogen consumption is physiologically related to cellular activity. Over activity of muscle results in excessive glycogen consumption, leading to glycogen depletion. The increased muscle activity and diminished blood supply, following connective tissue changes; owing to extensive oral submucous fibrosis leads to muscle degeneration and fibrosis.
 - *Nutritional deficiency*—the disease is characterized by repeated vesiculations and ulcerations of oral cavity. A sub-clinical vitamin B complex deficiency has been suspected in such cases. The deficiency could be precipitated by the effect of defective nutrition due to impaired food intake in advanced cases and may be the effect, rather than the cause of the disease.
- *Defective iron metabolism*—microcytic hypochromic anemia with high serum iron have been reported in submucous fibrosis but as such, there is no definite proof available to support this cause effect relation.
- *Bacterial infection*—streptococcal toxicity is also a factor in etiology of oral submucous fibrosis, as in some other collagen disorder such as rheumatic disease. *Klebsiella rhinoscleromatis* may be a factor in cause of submucous fibrosis.
- *Collagen disorders*—oral submucous fibrosis is thought to be localized collagen disease of oral cavity. It is linked to scleroderma, rheumatoid arthritis, Dupuytren's contracture and intestinal fibrosis. A link between scleroderma and oral submucous fibrosis has also been suspected on the basis of similarity of histological characteristic.
- *Immunological disorders*—raised ESR and globulin levels are indicative of immunodeficiency disorder. Serum immunoglobulin levels of IgA, IgG and IgM are raised significantly in oral submucous fibrosis. These raised levels suggest an antigenic stimulus in the absence of any infection. Circulating auto-antibodies are also present in some cases of oral submucous fibrosis.
- *Altered salivary composition*—the study of saliva in cases of oral submucous fibrosis have shown increased pH, increase in salivary amylase, low levels of calcium, increase in alkaline phosphatase and potassium and normal levels of salivary immunoglobulin. The fibrin precipitating factor in saliva has been attributed to the increased plasma fibrinogen. This is likely due to increased dietary content of fibrin.
- *Genetic susceptibility*—the familial occurrence of oral submucous fibrosis has also been reported (**Fig. 12-39**).

Clinical Features

- *Age and sex distribution*—it affects both sexes. The age group varies, although majority of patients are between 20 and 40 years of age.
- *Site distribution*—the most frequent location of oral submucous fibrosis is the buccal mucosa and the retro-molar areas. It also commonly involves soft palate, palatal fauces, uvula, tongue and labial mucosa. Sometimes, it involves the floor of mouth and gingiva.
- *Prodromal symptoms*—the onset of the condition is insidious and is often of 2 to 5 years of duration. The most common initial symptom is burning sensation of oral mucosa, aggravated by spicy food, followed by either hypersalivation or dryness of mouth. Vesiculation,

Fig. 12-39: Familial oral submucous fibrosis (OSMF) affecting daughter of patient who is also having OSMF.

ulceration, pigmentation, recurrent stomatitis and defective gustatory sensation have also been indicated as early symptoms.

• *Late symptoms*

- *Trismus*—gradual stiffening of the oral mucosa occurs in few years after the initial symptoms appear. This leads to inability to open the mouth completely (Fig. 12-40).
- *Difficulty in tongue protrusion*—later on, patients experience difficulty in protruding the tongue.
- *Difficulty in swallowing*—when the fibrosis extends to pharynx and esophagus, the patient may experience difficulty in swallowing the food.
- *Referred pain*—referred pain in the ears and deafness, due to occlusion of Eustachian tube and a typical nasal voice has been reported.

Fig. 12-40: Reduced mouth opening in oral submucous fibrosis (OSMF) (Courtesy Dr Suwas Darvekar).

- *Blanching of mucosa*—the most common and earliest sign is blanching of mucosa, caused by impairment of local vascularity (Fig. 12-41). The blanched mucosa becomes slightly opaque and white. The whitening often takes place in spots so that the mucosa acquires a marble like appearance. Blanching may be localized or diffuse, involving greater part of the oral mucosa or reticular, in which blanching consists of blanched area with intervening clinically normal mucosa, giving it a lace-like appearance.

Fig. 12-41: Blanched palate seen in OSMF.

- *Betel chewer mucosa*—it is brownish red discoloration of mucosa with irregular surface that tend to desquamate.
- *Fibrous band*—As disease progresses the mucosa becomes stiff and vertical fibrous band appears. This band can be palpate easily and feel rough on palpation.
- *Lips features*—mucosa is blanched, becomes rubbery and is characterized by the presence of circular bands around the rima oris like a thin band (Fig. 12-42). In severe labial

Fig. 12-42: Circular band seen around the rima oris in patient with oral submucous fibrosis (OSMF).

involvement, the opening of mouth is altered to an elliptical shape (elliptical rima oris), lips become leathery and it become difficult to evert them.

- *Buccal mucosa*—the affected mucosa becomes coarse, blanched and inelastic. In advanced cases, the mucosa becomes tough and leathery with numerous vertical fibrous bands (Fig. 12-43).

Fig. 12-43: Blanched fibrous band seen in buccal mucosa (Courtesy Dr Bhaskar Patle),

- *Soft palate (49%) and uvula*—involvement of soft palate is marked by fibrotic changes and a clear delineation of the soft palate from hard palate. The mobility of soft palate is restricted. Uvula, when involved, is shrunk and in extreme cases it becomes bud-like or hockey stick appearance (Figs 12-44 and 12-45).

Fig. 12-44: Bud-like appearance seen of uvula in oral submucous fibrosis (OSMF) (Courtesy Dr Bhaskar Patle).

- *Palatal fauces*—In the soft palate the bands radiate from pterygomandibular raphe to the anterior faucial pillars. The faucial pillars become thick and short and tonsils may get pressed in between fibrosed pillars.

Fig. 12-45: Hockey stick appearance of uvula seen in oral submucous fibrosis (OSMF) (Courtesy Dr Parate).

- *Tongue*—The initial change is depapillation, usually in the lateral margins. Tongue becomes smooth (Fig. 12-46); its mobility, especially in protrusion, becomes impaired. Patient cannot protrude the tongue beyond the incisal edges.

Fig. 12-46: Smooth tongue appears due to depapillation in case of oral submucous fibrosis.

- *Floor of mouth*—when floor of mouth is affected, it becomes inelastic.
- *Gingiva*—when affected, it becomes fibrotic, blanched and inelastic.
- *Associated features*
 - *Pigmentation*—hyperpigmentation or occasional loss of pigmentation is very common in association with oral submucous fibrosis. Many times pigmentation changes in vermillion border are so striking that this disease can be suspected even before examining the patient.
 - *Vesicle*—it is usually found in areas of redness in the soft palate, the anterior faucial pillar, buccal mucosa

or the mucosal surface of lip, particularly the lower lip. The vesicles are painful and they soon rupture leaving behind superficial ulceration. Often there is history of vesiculation following the intake of spicy food, suggesting an allergic reaction to spicy food.

- *Ulceration*—ulceration often develops in the course of disease, particularly in advanced cases. In advanced cases, epithelium becomes atrophic, fragile and vulnerable to ulceration (**Fig. 12-47**).

Fig. 12-47: Ulceration seen in oral submucous fibrosis.

- *Petechiae*—these are small raised reddish blue spots which sometimes occur in oral submucous fibrosis. It may be few or many. They occur most commonly on tongue and the labial and buccal mucosa. The petechiae are transient in nature and do not require any specific treatment.

Clinical Stages of Oral Submucous Fibrosis (Table 12-2)

- *Stage of stomatitis and vesiculation*—this is the earliest stage and is characterized by recurrent stomatitis and vesiculation. Patient complains of burning sensation in the mouth and inability to eat spicy food. The examination reveals vesicle formation particularly on the palate. They may rupture and superficial ulceration may be seen, which may cause painful mastication. Some amount of fibrosis is seen in this stage and mucosa shows whitish streaks. An occasional granulating red spot may be seen on the palate.
- *Stage of fibrosis*—the patient complains of stiffness and inability to open the mouth completely. As the disease progresses, there is difficulty in blowing out the cheeks. Tongue movement becomes restricted and protrusion of tongue is difficult. Complaints of pain in the ear may

Table 12-2: Clinically grading of oral submucous fibrosis according to its severity

Features	Grade I incipient (Very early stage)	Grade II (Mild)	Grade III (Moderate)	Grade IV (a) (Advanced stage)	Grade V (b) (Advanced pre-malignant and malignant change)
Symptoms	Burning sensation, dryness of mouth, vesicle or ulceration	Burning sensation, dryness of mouth	Burning sensation, dryness of mouth	Burning sensation, dryness of mouth	All classical sign of oral submucous fibrosis and it is associated with leukoplakia and Lichen Planus
Spicy food	Irritation with spicy food	Irritation with spicy food	Irritation with spicy food	Irritation with spicy food	
Mucosal color	No changes in mucosal color	Mucosa is blanched and loses its elasticity	Blanched opaque leather-like mucosa	Blanched opaque leather-like mucosa	
Fibrosis	No fibrosis, bands palpable	No clear-cut fibrotic bands	Vertical fibrotic bands on buccal mucosa making it stiff	Thick fibrosed bands occurring on both the buccal mucosa in retromolar area and at pterygomandibular raphe	
Mouth opening	Mouth opening normal (44 mm)	Slight restriction of mouth opening (26-35 mm)	Considerable restriction of mouth opening (15-25 mm)	Very little mouth opening (2-15 mm)	
Tongue	Tongue protrusion normal	Tongue protrusion normal	Tongue protrusion not much affected	Restricted tongue protrusion	
Eating and speaking	—	—	Difficulty in eating and speaking	Eating and speech very much impaired	
Oral hygiene	—	—	Poor oral hygiene	Very poor oral hygiene	

occur occasionally. Speech may become muffled and indistinct due to restriction of jaw movement. Due to restricted palatal movement, a nasal twang may occur in speech. The examination reveals increased fibrosis of submucosal tissue, which appears blanching and white. The lip and cheek become stiff and the vestibule of mouth is gradually reduced and almost obliterated. This causes difficulty even in introducing the examining fingers in between lips, cheeks and teeth in advanced cases. The palate shows blanching and fibrosis which cause shortening and disappearance of uvula in advanced cases. The fibrotic bands extending from palate to tongue cause strangulation of tonsils and they appear buried in the faucial pillars. The dorsum of tongue shows atrophy of papillae. The mucosa of the floor of mouth beneath the tongue, also show blanching and stiffness.

- *Stage of sequelae and complications*—the patient presents with complaints as described above in stage II. On examination, evidence of whitish leukoplakic changes and rarely an ulcerating malignant lesion may be seen.

Diagnosis

- *Clinical diagnosis*—clinically reduced mouth opening with palpable fibrous band is enough to make diagnosis.
- *Laboratory diagnosis*—oral epithelium is markedly atrophic which exhibits intercellular edema, signet cells, and epithelial atypia. The inflammatory cells are mostly mononuclear; eosinophils and occasional plasma cell may be seen.

Malignant Potential

Atrophic epithelium first becomes hyperkeratotic and later, intracellular edema and basal cell hyperplasia develop eventually, following epithelial atypia with moderate epithelial hyperplasia and then, carcinoma can develop at any time (**Fig. 12-48**).

The WHO Collaborating Centre for Oral Precancerous Lesions has concluded that although oral submucous fibrosis predisposes to cancer, it is not absolutely conclusive. It is highly probable that such relationship does exist. Following facts support this hypothesis:

- The frequency of oral leukoplakia in oral submucous fibrosis patient is 6-8 times higher than in control group.
- Carcinoma patients exhibiting oral submucous fibrosis have a frequency which exceed the 1.2% of submucous fibrosis in general population.
- Immunological alterations observed in oral submucous fibrosis are almost similar to that observed in oral cancer.

Fig. 12-48: Oral submucous fibrosis (OSMF) turning malignant which shows ulcerative growth in the oral cavity (Courtesy Dr Chole).

Management

Restriction of habit/behavioral therapy

The preventive measure should be in the form of stoppage of habit, which can be encouraged through public education. Affected patients should be explained about the disease and its possible malignant potential. Improvement in clinical features like gradual increase in inter-incisal opening has been observed in most of the patients who discontinue the habit.

Medicinal therapy

Supportive treatment

- *Vitamin rich diet*—a vitamin rich diet along with iron preparation is helpful to some extent but has little therapeutic value in relieving trismus.
- *Iodine B complex preparation*—iodine-B-complex preparation (Injection Ranodine) is a combination of iodine preparation with synthetic vitamin B complex. The combination of iodine compound with vitamin B complex is responsible for the stimulation of metabolic process and enzymatic process within the body (oxygen reduction, transamination). Intramuscular injection starts with small doses and continuing with larger doses (2 ml ampule daily). The course of 5 injections is repeated after 7 days. Each 2 ml consists of:
 - *Methyltrioxyethyl iodamine*—progressive increasing doses equivalent to 0, 25, 50, 75 and 125 mg of active iodine
 - *Vitamin B₁*—1.0 mg
 - *Vitamin B₆*—0.3 mg
 - *Vitamin B₂*—0.6 mg
 - *Nicotinamide*—15.0 mg
 - *Calcium pantothenate*—1.0 mg

- *Injection of arsenotyphoid and iodine*—arsenotyphoid is a fibrin dissolving agent.

Steroids

- *Local*—hydrocortisone injection along with procaine hydrochloride injection locally in the area of fibrosis. Injections are given fortnightly. The early cases show good improvement with this therapy.
- *Systemic*—A therapy with hydrocortisone 25 mg tablet, in doses of 100 mg/day is useful in relieving burning sensation without untoward effects. Triamcinolone or 90 mg of dexamethasone can be given. This is supplemented with local injection of hydrocortisone 25 mg at biweekly intervals at the affected site. Increased vascularity of the site is observed, which is attributed to fibrinolytic, anti-allergic and anti-inflammatory action of corticosteroid. The fibrosis is prevented by decreasing fibroblastic production and deposition of collagen.

Placental extract

- *Mechanism*—placentrax is an essential biogenic stimulator. It is suggested that it stimulates pituitary adrenal cortex and regulates metabolism of tissue. It also increases the vascularity of tissues. Its use is based on tissue therapy, which states that “animal and vegetable tissue when severed from the parent body and exposed to unfavorable conditions but not mortal to their existence, undergo biological re-adjustment leading to development of substances in state of their survival to ensure their vitality”. Such tissue extracts when implanted into body stimulate metabolic or regenerative process favoring recovery.
- *Placental extract contains*
 - *Nucleotides*—ribonucleic acid (RNA) and adenosine triphosphate (ATP).
 - *Enzymes*—alkaline and acid phosphatase, glutamic oxaloacetic acid transaminase, glutamic acid and pyruvic acid.
 - *Vitamins*—vitamin E, B, B₆, B₁₂, pantothenic acid, nicotinic acid, biotin PABA and folic acid.
 - *Steroids*—17, ketosteroid.
 - *Fatty acids*—linoleic acid, linolenic acid, palmitic acid.
 - *Trace elements*—copper, selenium, magnesium.
- *Form*—placental extract can be separated into four different factors i.e. aqueous extract, lipid extract, immune gamma globulin and tissue coagulated.
- *Placenta as biogenic stimulator*—only the aqueous extract of placenta acts as biogenic stimulator. It accelerates cellular metabolism, aids in absorption of exudate, and stimulates regenerative process, increases physiological function of organs, produces significant enhancement of wound healing and it has notable anti-inflammatory effect.

- *Dose*—the region affected with submucous fibrosis is divided into five regions. Each region is locally injected around fibrous bands, intra-muscularly, at the interval of 3 days for 15 days. Each time 2 ml solution is deposited. This course can be repeated after a month, if required.

Hyaluronidase

- *Mechanism*—improvement in health of mucous membrane, burning sensation and trismus was observed by using hyaluronidase injection. Hyaluronidase, by breaking down hyaluronic acid (ground substance of connective tissue), lowers the viscosity of intracellular cement substance i.e. hyaluronidase decreases cell formation by virtue of its action on hyaluronic acid, which plays an important role in collagen formation.

Lycopene

- *Content*—it is an antioxidant from tomato extract, along with other previously used antioxidants in the treatment of OSMF.
- *Dose*—tab Lycopene 2000 mcg. The drug will be given for a period of three months duration during which time patient will be reexamined every 15 days.

Vitamin E

- *Mechanism*—the use of vitamin E along with dexamethasone and hyaluronidase injections is thought to produce better results. Vitamin E presumably works by—
 - Preventing the oxidation of essential cellular constituents such as the formation of oxidation product.
 - Protecting against various drugs, metals and chemicals and acts as scavenger of free radical.
 - It may improve the survival of erythrocytes.

Other therapies

- *Vasodilator injection*—vasodilator injection, which relieves the ischemic effect and helps the nutritional and therapeutic measures to reach the affected tissue, with use of fluorouracil an anti-metabolic agent.
- *Injection of interferon gamma*—This is recently discovered therapy. Intralesional injection of interferon gamma improved mouth opening and reduce mucosal burning.

Surgical treatment

Conventional

- *Indication*—surgical treatment is the method of choice; when there is marked limitation of opening of the mouth, in cases where biopsy reveals neoplastic changes and when there is marked trismus and dysphagia. Various authors suggest different approaches.
- *Flap use as graft*—excision of fibrous bands followed by use of tongue flap as a graft gives good results because

tongue flap is highly vascular and resists further fibrosis. The most significant fact is that the tongue mucosa is immune to fibrosis whatever the cause. The aims are to relieve trismus, to prevent further fibrosis and to provide neovascularization of fibrous tissue. It is done in patients who have got mouth opening less than 1.5 cm, in cases of failure of conservative treatment and absence of any other pathology like ulceration, infection and leukoplakia.

- *Implantation of fresh human placenta*—in some cases, submucosal implantation of bits of fresh human placenta into the defect is done following the surgical excision of fibrous bands. The rationale for using placental graft is that they have both, hormonal and mechanical effects. They have stimulant effects because the placenta is homograft that is immunologically competent and rich in steroids, proteins, gonadotrophin, estrogen and progesterone. The graft undergoes local absorption after prolonged period, thus mechanically prevent fibrosis.
- *Nasolabial flap*—the excision of fibrotic bands is followed by reconstruction using bilateral full thickness nasolabial flap.
- *Bilateral palatal flap*—new technique is bilateral palatal flap to cover the exposed area, in combination with bilateral temporalis myotomy and coronoidectomy. After releasing fibrous bands, the anterior border of ramus is exposed. Temporalis tendon and muscle are detached and then coronoidectomy is performed bilaterally.
- *Oral stent*—use of oral stent as adjunct to treatment of oral submucous fibrosis. A stent is an appliance made up of acrylic having posterior vertical stops bilaterally. It is made prior to surgery up to desired increase in mouth opening, to allow the tissue to heal at new height. It is considered especially when the surgical technique is prone to relapse.

Laser

- *Mechanism*—the use of laser for treatment of submucous fibrosis is useful. CO₂ laser surgery offers advantage in alleviating the functional restriction, when compared to traditional surgical technique and subsequent grafting.
- *Technique*—under general anesthesia a CO₂ laser is used to incise the buccal mucosa and vaporize the submucosal connective tissue to the level of the buccinator muscle. Hemostasis is provided by lased surface itself and the mouth opening increases immediately.

Cryosurgery

- *Mechanism*—it is the method of local destruction of tissue by freezing it *in situ*. Open liquid sprays are better suited for mucosal lesion that are extensive and superficial and do not involve the basement membrane.

Oral Physiotherapy

Oral exercises are advised in early and moderately advanced cases. This includes mouth opening and ballooning of mouth. This is thought to put pressure on fibrous bands. Forceful mouth opening have been tried with mouth gag and acrylic surgical screw.

Diathermy

Microwave diathermy is useful in some early or moderately advanced stages. Low current is used (20 watts × 2450 cycles). It acts by physiofibrinolysis of bands. Its value is increased if it is combined with other treatment modalities.

Dyskeratosis Congenita

It is also called as 'Zinssner-Engman-Cole syndrome'. It is a well recognized but rare genokeratosis, which is probably inherited as a recessive characteristic. Mutation in DKC 1 gene will cause disruption in maintenance of telomerase which is critical in determining the normal cellular longevity. Disease manifested has three typical signs: oral leukoplakia, dystrophy of nails and pigmentation of skin.

Clinical Features

- *Age and sex distribution*—it is evident during first 10 years of life. It is almost exclusively seen in males.
- *Nail changes*—nail changes are the first manifestation, becoming dystrophic and shedding some time after the age of 5 years (**Fig. 12-49**).
- *Pigmentation*—grayish brown pigmentations appear in some time which is seen usually on trunk, neck and thigh.
- *Skin*—the skin may become atrophic, telangiectatic and face appears red.

Fig. 12-49: Dystrophy of nails seen in dyskeratosis congenita.

- *Thrombocytopenia*—it is developed during second decade of life.
- *Other features*—other minor manifestations are frail skeleton, mental retardation, small sella turcica, dysphagia, transparent tympanic membrane, deafness, epiphora, eyelid infection, urethral anomalies, small testes and hyperhydrosis of the palms and soles.

Oral Manifestations

- *Sites*—most common sites are tongue and buccal mucosa.
- *Appearance*—it appears as diffusely distributed vesicles and ulcerations, followed by accumulation of white patches of necrotic epithelium and sometimes, superimposed monilial infection. There is also atrophy of tongue (Fig. 12-50).
- *Recurrent ulceration*—after some time, in the age group of 14 to 20 years, there are repeated recurrent ulceration and development of erythroplasia or red mucosal lesion.
- *Erosive leukoplakia*—finally between the age of 20 and 30 years, there is development of erosive leukoplakia and carcinoma.

Fig. 12-50: Atrophy and hyperkeratinization seen in dyskeratosis congenita.

Radiographic Feature

- There may be severe periodontal bone loss.

Diagnosis

- *Clinical diagnosis*—leukoplakic type lesion associated with nail changes and pigmentation will diagnose dyskeratosis congenita.
- *Laboratory diagnosis*—the skin lesion shows increased number of melanin containing chromatophores and increased vascularity. There is anemia, leukopenia, thrombocytopenia and pancytopenia.

Management

- *Periodic check up*—periodic check up should be done for evidence of malignant transformation.

Lupus Erythematosus

It is characterized by presence of abnormal antibodies and immune complex.

Types

- *Discoid or cutaneous lupus erythematosus*—if it is confined to skin and mucosa.
- *Systemic lupus erythematosus*—if multiorgan involvement occurs.

Etiology

- *Genetic predisposition*—relative of patients have higher incidences of auto-antibodies, immune deficiency and connective tissue disease. This tendency is greatest among identical twins.
- *Immunological abnormality possibly mediated by viral infection*—immune complex consisting chiefly of nucleic acid and antibody account for majority of the tissue changes.
- *Autoimmune disease*—as these patients develop antibodies to many of their own cells.
- *Endocrine*—there is high incidence in females in pregnancy. This finding suggestive of increased estrogen level.
- *Biochemical increase* in excretion of metabolic products, particularly tyrosine and phenylalanine, in certain SLE patient.

Discoid Lupus Erythematosus

Clinical Features

- *Age and sex*—it occurs in 3rd and 4th decades, female predilection in the ratio of 5:1.
- *Site*—most common sites are face, oral mucosa, chest, back and extremities.
- *Appearance*—it is a circumscribed, slightly elevated, white patch that may be surrounded by red telangiectatic halo.
- *Cutaneous lesion*—cutaneous lesions are slightly elevated, red or purple macules; that are often covered by gray or yellow adherent scales.
- *Carpet track extension*—forceful removal of scale results in 'carpet track extension', which has dipped into enlarged pilosebaceous canals.
- *Peripheral growth*—the lesion increases in size by peripheral growth. Periphery of the lesion appears pink or red, while the center exhibits an atrophic scarred appearance.
- *Butterfly distribution*—butterfly distribution on macular region and across the bridge of the nose.

Oral Manifestations

- *Sites*—most common sites are buccal mucosa, tongue, palate and vermilion border of lip.

- *Symptoms*—there may be burning and tenderness which may be intermittent or disappears if the lesion becomes inactive.
- *Appearance*—it begins as erythematous area, sometimes slightly elevated, but more often depressed, usually with induration and typically with white spots. Occasionally, superficial painful ulceration may occur with crusting or bleeding, but no actual scale formation is seen.
- *Margins*—the margins of the lesion are not sharply demarcated. Fine white striae radiate out from the margins.
- *Central healing*—central healing may result in depression.
- *Lip*—erythematous, atrophic plaque, surrounded by keratotic border may involve the entire lip.

Systemic Lupus Erythematosus

Clinical Features

- *Age and sex*—it occurs in 3rd (female) and 4th (male) decades and has female predilection (8:1).
- *Sites*—it is characterized by repeated remissions and exacerbations with common sites being face, neck, upper arm, shoulders and fingers.
- *Symptoms*—it is manifested by symptoms of fever and pain in the muscle and joints. It may show as itching or burning sensation as well as area of hyper-pigmentation. Severely intensifies after exposure to sunlight.
- *Butterfly distribution of lesion on face*—the cutaneous lesion consists of erythematous patches on the face, which coalesce to form roughly symmetrical pattern over the cheeks and across the bridge of the nose, is called butterfly distribution.
- *Skin lesions*—skin lesions are widespread, bilateral with signs of acute inflammation. This finding helps to differentiate between skin lesions of DLE and SLE.
- *Kidney involvement*—in kidney, fibrinoid thickening of glomerular capillaries producing the characteristic 'wire loop' which may be sufficient to result in renal insufficiency.
- *Heart involvement*—heart may suffer a typical endocarditis involving valves as well as fibrinoid degeneration of epicardium and myocardium.

Oral Manifestation

- *Site*—the most common sites are buccal mucosa, lip and palate.
- *Symptoms*—complain of burning sensation, xerostomia or soreness of mouth.
- *Signs*—lesions similar to DLE, except that hyperemia, edema and extension of lesion is more pronounced.

Greater tendency to bleed and petechiae, suspected ulcerations surrounded by red halo.

- *Appearance*—the intraoral lesion is composed of a central depressed red atrophic area surrounded by 2 to 4 mm elevated keratotic zone that dissolves into small white lines (**Figs 12.51 and 12.52**).
- *Lupus cheilitis*—the lip lesions appear with central atrophic area with small white dots surrounded by keratinized border, which is composed of small radiating white striae. There is occasional ulceration of central area.

Fig. 12-51: Intraoral lesion of systemic lupus erythematosus showing atrophic area (Courtesy Dr Chole).

Fig. 12-52: Same patient (Fig. 12-51) having lesion present on palate (Courtesy Dr Chole).

Diagnosis

- *Clinical diagnosis*—skin lesion with lesion present on oral mucosa which is atrophic and erythematous will suspect lupus erythematosus. Oral and nasopharyngeal ulceration is major diagnostic criteria for SLE.

- *Laboratory diagnosis*—L.E. cell inclusion phenomenon with surrounding pale nuclear mass apparently devoid of lymphocytes. Anemia, leukopenia and thrombocytopenia, with sedimentation rate increased. Serum gamma globulin increased and Coomb's test is positive.
- *Positive lupus band test*—it shows deposition of IgG, IgM or complement component in skin.

Dental Consideration

- *Thrombocytopenia*—it may be sometimes severe. The result of a recent platelet count should be studied before undertaking oral surgery.
- *Bacterial endocarditis*—Libman-Sacks vegetation under the mitral valve may occur in patients with SLE, it can lead to bacterial endocarditis. So patients with SLE should have antibiotic prophylaxis before dental treatment that is likely to cause bacteremia.
- *Exacerbation by drug therapy*—drugs that have been related to exacerbation include penicillin, sulfonamide and NSAIDs with photosensitizing potential.
- *Exacerbation by surgery*—all elective surgeries including dental procedure to be avoided.
- *Susceptibility to shock and infection*—patients with SLE may be taking adrenal suppressive dose of corticosteroids or cytotoxic drugs and hence, they may be susceptible to shock and infection.

Differential Diagnosis

- *Lichen planus*—homogenous picture, no dark erythema and no telangiectasia. Mucosal changes are usually extensive and symmetrical.
- *Lichenoid reaction*—history of drug is always there.
- *Ectopic geographic tongue*—systemic manifestation present is lupus erythematosus, which is absent in ectopic geographic tongue.
- *Psoriasis*—Auspitz's sign is positive.
- *Electrogalvanic lesion*—dissimilar restorations are seen in oral cavity.
- *Leukoplakia and erythroplakia*—lesions tend to maintain same appearance and there are no skin changes.
- *Geographic stomatitis*—no skin changes, mucosal lesions change location rapidly.
- *Benign mucous membrane pemphigoid*—no systemic complain and serology test to be done.

Management

- *Corticosteroid*—systemic lupus erythematosus should be treated by systemic corticosteroids therapy and should be managed by physician. Discoid lupus erythematosus should be treated with topical steroid.
- *Anti-malarial drugs*—anti-malarial drug like hydroxychloroquine combined with nonsteroidal anti-inflammatory agents is also effective treatment modality.

- *Prevention*—patient should avoid exposure to sunlight as this can aggravate the conditions.

Cysts of Jaw

Introduction

Cyst has been known to arise in man (ever since he has teeth) and in certain animals. It takes some odontogenic epithelium plus some unknown initiating factor which stimulates it to proliferate to cause this destructive lesion, which can be found from the mildest form to a greatly disfiguring form.

Cysts of jaws are of great clinical importance, not only because they often attain a large size but also produce facial asymmetry, disturbance of dentition, neurological symptoms and predispose the jaws to fracture but particularly because they have a very high frequency of occurrence.

Definitions

- *By Killey and Key 1966*—this entity constituted an epithelium-lined sac filled with fluid or semifluid material.
- *By some unknown author 1966*—a cyst is an abnormal cavity in hard and soft tissue which contains fluid, semifluid, or gas and is often encapsulated and lined by epithelium.
- *By Kramer in 1974*—pathologic cavity having fluid, semifluid, or gaseous content but not always is lined by epithelium.

General Diagnostic Features of Cysts**Signs**

- *Factors affecting clinical features*—it usually depends on the extent and the dimension of lesion. A small cyst is unlikely to be diagnosed on routine examination because signs will not be demonstrable.
- *Expansion*—as the cyst grows larger, expansion of alveolar bone occurs, usually on the labial and buccal aspect of the jaw in case of a typical odontogenic cyst.

However, expansion of the lingual aspect alone can occur in case of cysts of ramus and third molar area. The expansion of both inner and outer bony wall is often indicative of lesion other than cyst.

- *Enlargement*—as the cyst increases in size, the periosteum is stimulated to form a layer of new bone which is subperiosteal deposition which later forms the outline of the affected portion of the jaw and produce enlargement.
- *Consistency*—at an early stage, the lateral expansion causes smooth, hard, painless prominence but as cyst growth proceeds, the bone covering the center of the convexity becomes thinned and can be indented with pressure. The term elastic is used to describe this particular consistency.
- *Window formation*—in some cases of expanding dental cyst there comes the time when the periosteum appears to be unable to maintain the new bone formation, resulting in an area where there is no bone, usually the summit of the convexity. This is called as ‘window’ formation. Window is more or less round and has a smooth margin which sometimes appears to be very slightly dense at periphery.
- *Egg shell crackling*—later the fragile outer shell of bone becomes fragmented and the sensation imparted and sound produced on palpation over the area is described as ‘egg shell crackling’.
- *Fluctuation*—in advanced cases, these sample pieces of bone disappear and are not replaced by new bone. At this point, the cyst lining lies immediately beneath the mucosa and fluctuation can be elicited.
- *Fluid discharge*—greater distension of the wall of the cyst leads to an eventual discharge of fluid into the mouth. This sequence of events is commonly observed with the progressive enlargement of periodontal and dentigerous cysts.
- *Site*—site of occurrence is also important in considering the diagnostic features. Periodontal cysts may

occur anywhere in the dental arch. Dentigerous cysts however are mainly associated with impacted molars and canines. Fissural cysts are confined to the upper jaw and the solitary bone cyst is virtually assigned to the mandible. Odontogenic keratocysts are most often seen in the lower third molar area extending into ramus.

- *Effect on teeth*—cysts rarely cause loosening of adjacent teeth until they become extremely large. The clinical absence of one or more teeth from normal series without a history of extraction may indicate the presence of developing dentigerous cyst. A single missing tooth may also invite suspicion of existence of odontogenic keratocyst or primordial cyst. The teeth adjoining an odontogenic keratocyst, fissural cysts or solitary cysts are vital. Apical periodontal cyst is associated with non-vital teeth, but in cases of lateral periodontal cysts the involved teeth often are vital.
- *Other features*—a large anterior cyst may extend under the nasal floor and cause distortion of nostril. Involvement of the antrum by an infected cyst may produce signs of maxillary sinusitis. In the jaw a cyst enlarging between teeth can cause their root to diverge and the crown to converge. Afterwards the teeth may tilt over one side.

Symptoms

- *Pain and swelling*—often the first symptom that patient experience is pain and swelling, if the cyst becomes infected. Sometimes the patient notices lump in the sulcus.
- *Anesthesia or paresthesia*—although large mandibular cysts invariably involve the neurovascular bundle and deflect structure into an abnormal position, still it is unusual to find anesthesia of the mental distribution. Since an uninfected cyst grows slowly and exerts a very slight pressure on the neurovascular bundle. However, in cases of acute infection there is a sudden increase in pressure due to pus accumulation in the sac and this can cause neuropraxia of the nerve and the immediate onset of labial paresthesia or anesthesia. After surgical drainage of infected cyst, sensation returns back to normal.
- *Salty taste*—when the cyst becomes secondarily infected and discharges into the mouth and when a sinus tract is present, then patient may complain of salty taste or a sinus tract is present.
- *Displacement of denture*—edentulous patients may seek treatment because of displacement of denture.
- *Tooth discoloration*—discoloration or loosening of tooth may prompt patients to visit the dentist.

Radiographic Features

- *View taken*—in the radiographic diagnosis of cysts of jaws, periapical and occlusal views are helpful. In addition, in case of large cysts, extraoral views provide an essential supplement to conventional intra-oral radiographs, which include lateral oblique, PA view for mandible, Waters' view and panoramic view (OPG).
- *Well defined radiolucency*—classically, radiographic appearance of a cyst is that of a well-defined round or oval areas of radiolucency circumscribed by a sharp radiopaque margin. Nevertheless, there is much variation to this standard pattern, which depends not only on the type of cyst but also on its location and the degree of bone destruction and expansion.

Other Diagnostic Features

- *Contrast study for cysts of the maxillary sinus*—in certain cases, like cysts in the maxillary sinus, use of contrast media, along with routine radiography is helpful in delineating the size and precise extent of the cyst. In this technique, the radio-opaque medium is injected into the maxillary sinus with an aspirating syringe. The mucosa is anesthetized and the needle is introduced into the maxillary sinus through the inferior meatus as for an aspiration biopsy of the sinus.
- *Ultrasonic diagnosis*—ultrasonography can be useful to give adequate information about the location and extent in depth of cysts. It is possible to make a diagnosis on the basis of the echo of an ultrasonic impulse and the margins of bone. It can also provide very interesting information for the diagnosis of conditions in the maxillary sinus.
- *Aspiration*—aspiration of a suspected cyst is a valuable diagnostic aid when doubt exists about the nature of lesion after careful clinical and radiographic examination. This examination is also helpful in distinguishing between maxillary sinus and maxillary cyst. Aspirate withdrawn from the cyst appears as straw colored fluid. Aspiration of air indicates penetration into the antrum. Failure to obtain air or fluid is an indication of a solid lesion.

Theories of Cyst Enlargement

The exact mechanism is not known, but it could be that the mechanism-governing enlargement of cysts of the jaws is the same irrespective of the type of cysts. The various steps involved in the formation of a cyst seem to be as follows:

- *Attraction of fluid*—the attraction of fluid into the cystic cavity.
- *Retention of fluid*—the retention of fluid into the cavity.

- **Raised hydrostatic pressure**—the production of raised internal hydrostatic pressure.
- **Resorption of surrounding bone**—the resorption of surrounding bone with an increase in the size of bone cavity.

Harries classified the theories of cyst enlargement in the following manner (**Fig. 13-1**)

- **Mural growth**
 - Peripheral cell division
 - Accumulation of cellular content
- **Hydrostatic enlargement**
 - Secretion
 - Transudation and exudation
 - Dialysis
- **Bone resorbing factor.**

Mural Growth

Peripheral cell division

- **Cell division of lining epithelium**—peripheral enlargement of cyst occurs due to active cell division of the lining epithelium. This is in response to an irritant stimulus. Cyst regression occurs following the removal of such stimulus.
- **Cons of theory**—the theory has been criticized on the basis that such regression would lead to an irregularly thickened inner surface because of the resistance of the surrounding bone. However, this ignores the possibility that the cyst wall is not only well supported by its fluid content but can also actively resorb bone sufficiently and rapidly to accommodate the expanding perimeter.

Accumulation of cellular content

- **Accumulation of mural squames**—Kramer has suggested that keratocyst enlarges by the increasing accumulation of mural squames which is the result of casting off the living epithelium. The characteristic finger-like projections of growth represents local areas of increased cell division. An alternative explanation for this elongation is that keratocyst although persistent in their growth are poor bone resorbers and simply extend preferentially along the less dense cancellous bone with little resorption and expansion of dense cortex.

Hydrostatic Enlargement

Growth of cyst occurs due to distension of the cystic wall by fluid that has accumulated by secretion, transudation and dialysis.

- **Secretion**—it occurs from goblet cells. Apart from the occasional goblet cells usually found in follicular cyst, there is little morphological evidence of intracystic secretion.

- **Transudation and exudation**—these have been proposed mainly for the enlargement of the follicular and periodontal cyst respectively. This conclusion was derived from an examination of the protein content and specific gravity of the cystic fluid. The presence of fibrin and cholesterol in periodontal and follicular cysts suggests that hemorrhage also contributed to the cystic fluid.
- **Dialysis**—the mean osmolality of the cystic fluid is 10 miliosmoles higher than that of serum. This gradient is attributed to the accumulation of the low molecular weight cells shed from the lining epithelium and maintained by inadequate lymphatic access to the cyst lumen, the consequence is net entry of fluid from the capsule capillaries into the cystic lumen.

Fig. 13-1: Theories of cyst enlargement—diagrammatic representation

Bone Resorbing Factor

- **Prostaglandin**—vital cyst tissue in culture has been shown to release a potent bone resorbing factor, which is predominately a mixture of prostaglandin E_2 (PGE_2) and prostaglandin E_3 (PGE_3).
- **Mechanism**—the source of this resorbing factor appears to be the capsule and leukocyte content. Prostaglandin

release is reduced in some cysts when the epithelium is removed before culture but it is not clear whether the reduction results from the removal of an epithelial inductive effect or it merely reflects the loss of prostaglandin produced within the epithelium.

- *How prostaglandin production take place*—the mechanism of prostaglandin production is not known. One possibility is that production takes place in the capsule under the influence of epithelial proliferation, lysosomal phospholipase from fibroblasts and polymorphonuclear leukocytes; breaking down of phospholipid cell membrane to produce arachidonic acid which is converted by the ubiquitous enzyme prostaglandin synthetase to prostaglandin.

Classification

It is described in Tables 13-1 to 13-4.

Table 13-1: Classification of cysts by Robinson (1945)

From odontogenic tissues

Periodontal cyst

- Radicular or dental root apex type
- Lateral type
- Residual type
- Dentigerous cyst
- Primordial cyst

From non-dental tissues

- Median cyst
- Incisive canal cyst
- Globulomaxillary cyst

Table 13-2: Classification of cysts by WHO ICD-DA 1995 (excludes radicular cyst and mucus cyst)

Developmental odontogenic cyst

- Primordial (keratocyst)
- Gingival cyst
- Eruption cyst
- Dentigerous cyst (follicular)
- Gingival cyst of adults
- Lateral periodontal cyst
- Glandular odontogenic cyst
- Sialo-odontogenic cyst

Developmental non-odontogenic cyst

- Nasopalatine duct (incisive canal) cyst
- Globulomaxillary cyst (nowadays it does not include in cyst)
- Median palatal cyst (nowadays it does not exist)
- Cyst of palatine papilla

Other cyst of jaw

- Aneurysmal bone cyst (nowadays it is recognized as variant of giant cell tumor)
- Traumatic bone cyst (hemorrhagic bone cyst)
- Epithelial jaw cyst (no identifiable as odontogenic or non-odontogenic)

Other cyst of oral region not elsewhere classified

- Dermoid cyst
- Epidermoid cyst
- Gingival cyst of newborn
- Palatal cyst of newborn
- Nasoalveolar cyst (nasolabial)
- Lymphoepithelial cyst

Cyst of oral region unspecified

Table 13-3: Classification of cysts by Gorlin (1964)

Odontogenic cysts

- Dentigerous cyst
- Eruption cyst
- Gingival cyst of newborn infants
- Lateral periodontal and gingival cyst
- Keratinizing and calcifying cyst
- Radicular cyst
- Primordial cyst
- Multiple cysts of jaws and multiple cutaneous nevoid basal cell carcinoma and skeletal anomalies

Non-odontogenic and fissural cysts

- Globulomaxillary cyst (premaxilla maxillary cyst)
- Nasoalveolar (Nasolabial Klestadt's) cyst
- Nasopalatine (median anterior maxillary) cyst
- Median mandibular cyst
- Anterior lingual cyst
- Dermoid and epidermoid cyst
- Palatal cyst of newborn infants

Cysts of neck and oral floor and salivary gland

- Thyroglossal duct cyst
- Lymphoepithelial (bronchial cleft) cyst
- Oral cysts with gastric or intestinal epithelium
- Salivary gland cyst
- Mucocele and ranula

Pseudocyst

- Aneurysmal bone cyst
- Static (developmental latent) bone cyst
- Traumatic (hemorrhagic solitary) bone cyst

Table 13-4: Classification of cysts by Shear

Epithelial

Odontogenic

Developmental

- Dentigerous cyst (follicular)
- Eruption cyst
- Primordial cyst
- Gingival cyst of adults
- Lateral periodontal cyst
- Calcifying odontogenic cyst

Inflammatory cyst

- Radicular cyst
- Residual cyst
- Inflammatory collateral cyst
- Paradental cyst

Non-odontogenic

- Nasopalatine duct (incisive canal) cyst
- Median palatine, median alveolar and median mandibular cysts
- Globulomaxillary cyst
- Nasolabial cyst

Non-epithelial

- Simple bone cyst (traumatic solitary hemorrhagic bone cyst)
- Aneurysmal bone cyst

Cysts associated with maxillary antrum

- Benign mucosal cyst of the maxillary antrum
- Surgical ciliated cyst of maxilla

Cysts of the soft tissue of the mouth, face and neck

- Dermoid and epidermoid
- Branchial cleft cyst (lymphoepithelial)
- Thyroglossal duct cyst
- Anterior medial lingual cyst
- Oral cyst with gastric or intestinal epithelium
- Cystic hygroma
- Cysts of salivary glands
- Parasitic cyst, hydatid cyst, cysticercosis cellulosa

Epithelial Developmental Odontogenic Cyst

Dentigerous Cyst

It is also called as 'follicular cyst' or 'pericoronal cyst'. It is the most common type of odontogenic cyst which encloses the crown of the unerupted tooth by expansion of its follicle and is attached to the neck. Most of dentigerous cysts are discovered by radiographs, when these are taken because a tooth is missing or teeth are tilted or out of alignment.

Origin

- *Fluid accumulation*—it is formed due to fluid accumulation in the layer of reduced enamel epithelium or between it and the crown of unerupted teeth.
- *Proliferation of epithelium in dental follicle*—it may originate initially by proliferation and cystic transformation of islands of epithelium in the connective tissue wall of the dental follicle or even outside the follicle and this transformed epithelium then unite with the lining of follicle epithelium forming a solitary cystic cavity around tooth crown.

Fig. 13-2: Dentigerous cyst seen as swelling in canine region in maxillary area—intraoral view (Courtesy Dr Ashok L).

Clinical Features

- *Age and sex*—as it arises from the follicle of an unerupted tooth, it is usually found in children and adolescents with a higher incidence in 2nd and 3rd decades. It is slightly more common in males.
- *Site*—it is most commonly associated with mandibular 3rd molars and maxillary canines (**Fig. 13-2**) which are most commonly impacted. It may also be found enclosing a complex compound odontome or involving a supernumerary tooth.
- *Symptoms*—generally, it is painless but may be painful if it gets infected. When dentigerous cyst expands rapidly to compress sensory nerve, it produces pain which may be referred to other sites and described as headache.
- *Size*—they vary in size from a little more than the diameter of the involved crown to an expansion that causes progressive but painless enlargement of jaws and facial asymmetry (**Fig. 13-3**).
- *Teeth*—teeth adjacent to the developing cyst and involved teeth may get severely displaced and resorbed. There may be displacement of third molars to such an extent that it sometimes comes to lie compressed against the inferior border of the mandible.
- *Pathological fracture*—in some cases, pathological fracture can occur.
- *Expansion*—the most important feature of these lesions is its potential to expand. Cystic involvement of an unerupted third molar may result in hollowing out of the entire ramus extending up to the coronoid process and condyle as well as the body causing expansion of cortical plates (**Fig. 13-4**). In the case of a cyst associated with maxillary cuspids, expansion of the anterior maxilla often occurs and may superficially resemble acute sinusitis or cellulitis.
- *Associated disease*—bilateral cysts are found in association with basal cell nevus syndrome, cleidocranial dysplasia and a rare form of amelogenesis imperfecta.
- *Blue domed cyst*—when it contains blood, then it is called as 'blue domed cyst'.
- *Complication*—there are several potential complications besides the possibility of recurrence following incomplete surgical removal. These include:
 - *Ameloblastoma*—the development of an ameloblastoma either from the lining epithelium of the cyst or rests of odontogenic epithelium in the wall of the cyst, are called as mural ameloblastoma.

Fig. 13-3: Large dentigerous cyst causing facial asymmetry in patient (Courtesy Dr Parate).

- *Mucoepidermoid carcinoma*—the development of mucoepidermoid carcinoma, which is a malignancy of salivary glands, associated with the lining epithelium or dentigerous cyst which contain mucous secreting cell.

Fig. 13-4: Expansion in patient of dentigerous cyst (Courtesy Dr Bhaskar Patle).

Radiographic Features

- *Radiodensity*—well defined radiolucency usually associated with hyperostotic borders unless they are secondarily infected and are usually seen around an unerupted tooth (**Fig. 13-5**).
- *Internal structure*—usually, it is unilocular but sometimes it may appear multilocular, this image is caused by ridges in the bony wall and not by the presence of bony septa.

Fig. 13-5: Dentigerous cyst present with hyperostotic border.

- *Margins*—The bony margins are well defined and sharp (**Fig. 13-6**). In case of infection, margins may be ill defined.
- *Teeth*—It may envelop the crown symmetrically, but it may expand laterally from the crown. Cyst is usually

Fig. 13-6: Dentigerous cyst showing well defined border present in the mandible (Courtesy Dr Bhaskar Patle).

attached with the cemento-enamel junction. Associated tooth may be displaced in any direction. Usually direction of displacement is in apical region. Teeth may be displaced in the coronoid process, high up above the tooth-bearing region of maxilla.

- *Resorption of root*—the large cysts are always confined to the mandible. There may be resorption of roots of adjacent teeth.
- *Maxillary antrum*—the floor of the maxillary antrum may get displaced if cyst encroaches upon it.
- *Bilateral dentigerous cyst*—in some cases, there may be presence of dentigerous cyst on both side of mandible.
- *Multiple dentigerous cyst*—in some cases, we may find multiple dentigerous cyst present in one patient (**Fig. 13-7**).
- *CT features*—it shows expansive process with sclerotic border (**Figs 13.8 and 13.9**).
- *MRI features*—it shows homogenous high signal content.

Fig. 13-7: Multiple dentigerous cyst present in mandible (arrow).

Fig. 13-8: CT scan of dentigerous cyst showing cyst associated with tooth.

Fig. 13-9: CT scan of dentigerous cyst present in posterior region of mandible (Courtesy Dr Iswar).

Radiographic Types

According to Thoma

- **Central variety**—in it, crown is enveloped symmetrically. In this instance, pressure is applied to the crown of the tooth and may push it away from its direction of eruption. In this way, the mandibular third molar may be found at the lower border of the mandible and in the ascending ramus and a maxillary canine in the sinus or as far as the floor of the orbit (Fig. 13-10). The maxillary incisors may be found below the floor of the nose.
- **Lateral type**—in it, dentigerous cyst is a radiographic appearance which results from dilation of the follicle on one aspect of the crown. This type is commonly seen when an impacted mandibular molar is partially erupted so that its superior aspect is exposed.
- **Circumferential type**—in it, the entire tooth appears to be enveloped by the cyst (Fig. 13-11). The entire enamel organ around the neck of the tooth becomes cystic often allowing the tooth to erupt through the cyst.

Fig. 13-10: Central variety of dentigerous cyst in which crown is enveloped by cyst.

Fig. 13-11: Circumferential type of dentigerous cyst showing tooth enveloped by the cyst.

According to Mourshed

- **Class I**—dentigerous cyst associated with completely unerupted teeth
 - Dentigerous cyst associated with unerupted teeth, who failure to erupt is due to lack of space in the dental arch.
 - Dentigerous cyst associated with unerupted teeth, who failure to erupt is due to mal-positioning of the tooth germ.
 - Dentigerous cyst associated with unerupted supernumerary teeth.
- **Class II**—dentigerous cyst associated with partially erupted teeth.

Diagnosis

- **Clinical diagnosis**—expansive swelling in the posterior region of mandible will give clue to the diagnosis.
- **Radiological diagnosis**—well defined radiolucency associated with impacted teeth with hyperostotic border and well defined margin will diagnose the dentigerous cyst.

- *Laboratory diagnosis*—biopsy shows thin connective tissue wall with a thin layer of stratified squamous epithelium lining the lumen. Rete pegs formation is absent. It also shows Rushton bodies within the lining epithelium which are peculiar linear and often curved hyaline bodies. Fluid can be aspirated from the dentigerous cyst (Fig. 13-12).

Fig. 13-12: Aspirated fluid from dentigerous cyst (Courtesy Dr Shetty).

Differential Diagnosis

- *Ameloblastoma and ameloblastic fibroma*—they are multilocular and not associated with crown of an unerupted tooth. They will grow laterally away from the tooth in comparison to dentigerous cyst, which envelopes the tooth symmetrically and it is more common in premolar and molar area. There is internal structure present in ameloblastoma and in case of dentigerous cyst, it is most unlikely.
- *Adenomatoid odontogenic tumor*—they are rare and occur in the maxillary anterior region.
- *Calcifying odontogenic cyst*—it may occur as pericoronal radiolucency and may contain evidences of calcification.
- *Developmental primordial and follicular primordial cyst*—it can also be considered in the differential diagnosis. It occurs in close proximity to the crown of unerupted teeth and superimposition of its image causing cyst like radiolucency can appear as dentigerous cyst on the radiograph. However, in cases of follicular primordial cyst, the cystic lining surrounds the crown, whereas in dentigerous cyst, it is attached to the neck of tooth. The diagnosis of primordial cyst can be confirmed by taking a radiograph with different angulations.
- *Hyperplastic follicle*—the size of the normal follicle is 2 to 3 mm. If the follicular space exceeds 5 mm a dentigerous cyst is more likely the diagnosis. Region should be reexamined after 6 months to see any increase in size and effect on surrounding teeth.
- *Odontogenic keratocyst*—it does not expand the bone as severely as dentigerous cyst and also is less likely resorbs the tooth. It is usually attached more apically than the dentigerous cyst.
- *Radicular cyst at apex of primary teeth*—it may surround the crown of developing permanent teeth giving the false impression of dentigerous cyst. In this case, clinician should look for deep carious lesion or extensive restoration of the primary teeth which may help in the diagnosis of radicular cyst of primary teeth.

Management

- *Surgical*—smaller lesions can be surgically removed with little difficulty. The larger cyst involves surgical drainage and marsupialization. This procedure results in relief of pressure and gradual shrinking of the cystic lesion by peripheral opposition of new bone.
- *Decompression*—small acrylic button or short section of rubber is placed in preformed surgical opening in cyst which keeps the opening open and permits drainage. Recurrence is relatively uncommon unless there has been fragmentation of the cystic lining with remnants allowed to remain.
- *Orthodontic treatment*—in cases when you want to retain the tooth, orthodontic movement of teeth should be carried out.

Eruption Cyst

A specific type of cyst, which must be classified as a form of dentigerous cyst, is frequently associated with the erupting deciduous or permanent teeth in children.

An eruption cyst is in fact a dentigerous cyst occurring when a tooth is impeded in its eruption within the soft tissues overlying the bone, whereas the dentigerous cyst develops around the crown of an unerupted tooth which is lying in the bone. This cyst has often been termed as 'eruption hematoma'.

Pathogenesis

- *Dilation of tooth follicle*—it is essentially a dilation of the normal tooth follicle caused by accumulation of tissue fluid or blood. In 11% of cases, it occurs during the eruption of incisors and in 30% of cases, it occurs during eruption of canines and molars.

Clinical Features

- *Appearance*—clinically the lesion appears as a circumscribed, fluctuant, often translucent swelling of the alveolar ridge over the site of eruption of the tooth.
- *Age*—it is most commonly seen in children younger than 10 years of age.
- *Site*—it is most commonly seen first permanent molar and maxillary incisors.
- *Eruption hematoma*—when the circumscribed cystic cavity contains blood, the swelling appears purple or deep blue, hence it is termed as 'eruption hematoma'.

Radiological Features

- *Expansion of follicular space*—expansion of the normal follicular space of erupting tooth crown is seen.
- *Saucer shape excavation*—in some cases, there is saucer shaped excavation of bone projecting (Fig. 13-13) very slightly into the cavity.
- *Margin*—margin is well defined.

Fig. 13-13: Saucer shaped excavation of bone seen in eruption cyst (Courtesy Dr Ashok L).

Diagnosis

- *Clinical diagnosis*—circumscribed soft fluctuant translucent swelling around first permanent molar or maxillary incisor may give clue to the diagnosis.
- *Radiological diagnosis*—saucer shaped excavation of bone with well defined margin.
- *Laboratory diagnosis*—lamina propria shows variable inflammatory cell infiltrated.

Management

- *Excision of roof of cyst*—this is simple procedure to permit tooth to erupt. In some cases, cyst rupture spontaneously to facilitate tooth eruption.

Odontogenic Keratocyst

The keratocyst was probably first described by Mikulicz in 1876. According to Pindborg and Hansen, the designation keratocyst was used to describe any jaw cyst exhibiting keratinization in their lining which may occur in follicular, residual and very rarely in a radicular cyst.

11% of all jaw cysts are OKC. OKC is not a clinical diagnosis but a designation for a group of cysts of possibly diverse origins which have a number of highly characteristic microscopic and clinical features in common with highest recurrence rate of any of the odontogenic cyst.

In general, thin connective tissue wall and thin squamous type epithelial lining (4 to 8 cell thick) that contains keratin is either para (87%) or ortho (13%) and without rete pegs.

The basal layer is either columnar or cuboidal epithelium and its prickle cells are present and they are vacuolated. In some cases, bud-like proliferation from the basal layer into adjacent connective tissue wall or proliferation of islands of odontogenic epithelium that may be present in the wall giving rise to satellite microcysts which support the fact that OKCs have a high recurrence rate. 5% of dentigerous and radicular cysts are keratocysts and a variety of many primordial, gingival, lateral periodontal and residual cysts are of keratocyst variety.

According to Browne, odontogenic keratocyst is a histopathological term and should be restricted to its original sense and to describe the nature of the cyst. To avoid confusion between primordial cyst and keratocyst, Browne said that the term primordial cyst should be restricted to describe the origin and odontogenic keratocyst should be restricted to describe the nature of the cyst.

Origin of Cyst

- *Dental lamina*—it possesses marked growth potential or alternatively from proliferation of basal cells as 'basal cell hamartomas'.
- *Remnants of oral epithelium*—a residue or remnants of oral epithelium. The epithelium of the odontogenic keratocyst has been shown to be far more active than most odontogenic cysts as judged by their greater mitotic activity.

Clinical Features

- *Age*—odontogenic keratocyst occurs over a wide age range and cases have been recorded as early as the first decade and as late as the ninth with age group 4 to 84 years. Initiated early in life, during the period of tooth development with a peak incidence in 2nd and 3rd decades.
- *Sex*—it is found more frequently in males than in females and this sex predilection is more pronounced in blacks than in whites.
- *Site*—it is more common in mandible with a greater incidence at the angle and extending for varying distance into the ascending ramus and forward into the body (Fig. 13-14).
- *Symptoms*—asymptomatic unless they become secondarily infected, in which case patient complains of pain, soft tissue swelling and drainage. Occasionally, they experience paresthesia of the lower lip or teeth. Paresthesia can also occur, if there is a pathological fracture.

Fig. 13-14: Odontogenic keratocyst present as swelling in ramus area (Courtesy Dr Bhaskar Patle).

- **Teeth**—teeth may be displaced, if it expands through cancellous bone and the body of the mandible.
- **Signs**—the lesion can lead to pathologic fracture. As these cysts grow in anteroposterior direction, there is no obvious bony expansion seen (Fig. 13-15).
- **Aspiration**—on aspiration there is odorless, creamy or caseous content.
- **Syndrome associated**—multiple odontogenic keratocyst are found in Gorlin-Goltz syndrome, Marfan syndrome, Ehlers-Danlos syndrome and Noonan's syndrome.

Fig. 13-15: OKC intraoral view showing swelling in retromolar area (Courtesy Dr Tapasya Karamore).

Radiographic Features

- **Site**—more than 90% are seen posterior to the canines in the mandible and more than 50% at the angle of the mandible.
- **Characteristic**—40% have a characteristic suggestive of dentigerous cyst, 25% suggestive of primordial cyst, 25% lateral periodontal cyst and 10% of globulomaxillary cyst.
- **Internal structure**—undulating borders with cloudy interior appearances suggestive of multilocularity (Fig. 13-16).

Fig. 13-16: OKC with undulating border and cloudy interior.

- **Size**—size varies and may be 5 cm or more in diameter. Maxillary lesions are smaller and rounder than those in the mandible.
- **Shape**—shape of cyst is usually oval extending along the body of the mandible with little mediolateral expansion.
- **Margins**—margins are hyperostotic.
- **Unilocular variety**—Majority of lesions are unilocular with smooth borders (Fig. 13-17) but some unilocular lesions are large with irregular borders. Radiolucency is usually hazy due to keratin filled cavity and it is surrounded by thin sclerotic rim due to reactive osteocytes.

Fig. 13-17: Unilocular variety of OKC showing hyperostotic border (Courtesy Dr Bande).

- *Anteroposterior extension*—radiolucency extend along the medullary spaces in the anteroposterior direction (**Fig. 13-18**). There may be extensive involvement of the body and ascending ramus of the mandible with little or no bony expansion (**Fig. 13-19**).

Fig. 13-18: Radiolucency extending in anteroposterior direction in OKC (Courtesy Dr Arijj).

Fig. 13-19: Extensive involvement of ramus and body of mandible in OKC.

- *Perforation of cortical plate*—in some cases it can perforate the buccal and lingual cortical plates of bone and involve the adjacent soft tissue.
- *Displacement of inferior alveolar canal*—downward displacement of the inferior alveolar canal and resorption of the lower cortical plate of the mandible may be seen as well as perforation of bone and a pathologic fracture may occasionally occur.
- *Teeth*—as the keratocyst enlarges it may produce deflection of unerupted teeth mostly in the region of the angle of the mandible and occasionally, on the ascending ramus and towards the orbital floor and in some cases, root resorption is also seen.
- *CT features*—it will demonstrate exact dimension of the radiolucency (**Fig. 13-20**).

Radiological Types of Keratocyst

- *Envelopment type*—it is referred to a variety of keratocyst which embraces an adjacent unerupted tooth.

Fig. 13-20: CT scan of OKC showing dimension of radiolucency (Courtesy Dr Iswar).

- *Replacement*—those which form in the place of normal teeth.
- *Extraneous*—those in the ascending ramus away from the teeth.
- *Collateral*—those adjacent to the root of teeth which are indistinguishable radiologically from the lateral periodontal cyst.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Radiological diagnosis*—radiolucency extending in anteroposterior direction with undulating border may be suggestive of OKC.
- *Laboratory diagnosis*—biopsy shows corrugated or wrinkled parakeratin surface. Prominent palisaded polarized basal cell layer often described as having a 'picket fence' or 'tombstone' appearance. Connective tissue shows daughter cysts or small satellite cysts.

Differential Diagnosis

It can be given in two ways:

Most likely

- *Ameloblastoma*—This usually occurs in older age. It is generally multilocular though a unilocular lesion may also occur. Mostly, it appears with paresthesia. As it is benign, it may show resorption of root with displacement. In cases of cyst, it shows amber colored fluid on aspiration.
- *Primordial cyst*—it is also common in third molar area. Absence of a tooth without a history of extraction favors primordial cyst. It also shows amber colored fluid on aspiration.

- *Residual cyst*—in cases of residual cyst, patient gives a history of extraction of tooth. Most of residual cysts are unilocular. A thin radio-opaque margin is common, although those infected will not have such a well defined margins. It shows amber colored fluid on aspiration.
- *Traumatic cyst*—the most characteristic radiographic feature of the cyst is the scalloped margins. Mostly, it appears unilocular. The lesion rarely causes cortical plate expansion but when this occurs it is mostly on buccal side. There may be history of trauma. In most cases, it is asymptomatic. Needle aspiration is usually non-productive. Only a few milliliter of straw colored or serosanguinous fluid can be withdrawn.

Less likely

- *Benign odontogenic tumor and cementifying or ossifying fibroma*—these are not common lesions.
- *Giant cell granuloma*—it is usually found in the anterior region of the jaw.
- *The giant cell lesion of hyperparathyroidism*—it can often be ruled out by studies on serum chemistry.
- *Tooth crypt*—the possibility of radiolucency of tooth crypt is less likely as calcification of the tooth starts in the 8th year of age. The halo has thin outer radio-opaque border which is continuous with the lamina dura in the area of the cemento enamel junction.
- *Odontogenic myxoma*—rarely myxoma must be considered in such circumstances because the tooth has failed to develop and may be seen as a cyst-like radiolucency.

Management

- *Enucleation*—enucleation of entire cyst with vigorous curettage of the cystic wall. Periodic post-treatment examination should be done.
- *Peripheral osteotomy*—peripheral osteotomy of bony cavity can be done to reduce chances of recurrence.
- *Chemical cauterization*—chemical cauterization of bony cavity with intraluminal injection of Carnoy's solution allow freeing the cyst from bony wall which in turn allow easier removal of cyst.
- *Decompression*—this is achieved with the help of polyethylene drainage tube kept in the bony cavity.

Recurrence

Rate of recurrence of odontogenic keratocyst is very high. There are number of reasons for it.

- *Satellite cyst*—occurrence of satellite cyst, which is a bud-like projection of basal cell layer into the connective tissue. Cystic lining may be retained during the enucleation procedure.
- *New cyst formation*—some instances of recurrence are likely because of new cyst formation rather than true recurrence.

- *Difficult in enucleation*—secondarily, its lining is very thin and fragile particularly when the cyst is large and therefore it is more difficult to enucleate than a cyst with thick wall. Portion of the lining may be left behind and constitute the origin of recurrence. Enucleation in one piece may be more difficult with cysts which have a scalloped and thin margins and this may explain the higher recurrence rate than those with smoother contour.
- *Intrinsic growth potential*—Toller suggested that there may be an intrinsic growth potential in the epithelial lining which may be responsible for a higher recurrence rate.
- *Proliferation of basal cell*—it may arise from proliferation of the basal cells of the oral mucosa particularly in the third molar area and ascending ramus of the mandible. It is referred that there is often a firm adhesion of the cyst to overlying mucosa and it is recommended that mucosa should be excised with them in an attempt to prevent possible recurrence from the residual basal cell proliferation.

Adenomatoid Odontogenic Cyst

Adenomatoid odontogenic cyst is cystic hamartoma arising from odontogenic epithelium. In some cases, proliferations fill all the lumen space mimicking a solid tumor.

Clinical Features

- *Location*—it is seen in anterior region of the maxilla.
- *Age and sex distribution*—it is common in young age group with predilection for women.
- *Symptoms*—it is usually asymptomatic. In some cases, expansion of jaw occur which is also associated with pain.
- *Size*—some of the lesion may enlarge up to size of 10 cm.
- *Signs*—expansion can be palpated and facial asymmetry can be present due to swelling.

Radiological Features

- *Appearance*—it appears as well demarcated unilocular radiolucency associated with impacted tooth (**Fig. 13-21**).
- *Calcification*—calcification can be seen. In some cases, this calcification will appear as small pebbles appearance.
- *Effect on surrounding structure*—separation of roots or displacement of an adjacent tooth occurs frequently. There is also cortical expansion and root resorption. The lesion may inhibit the eruption of involved tooth.

Differential Diagnosis

- *Dentigerous cyst*—it is seen in 2nd to 4th decade as compared to adenomatoid odontogenic cyst which is

Fig. 13-21: Cystic radiolucency seen in anterior maxillary region suggestive of adenomatoid odontogenic cyst (Courtesy Dr Parate).

seen in young age. It is seen in posterior region as compared to adenomatoid odontogenic tumor which is seen in anterior region. Adenomatoid odontogenic tumor has tendency to surround more than just crown of the unerupted tooth.

- *Calcifying odontogenic cyst*—occurs in older age as compared to adenomatoid odontogenic tumor and mandibular premolar area is affected mostly.
- *Odontogenic fibroma or myxoma*—tennis racket pattern is seen.
- *Ameloblastic fibroma*—seen in premolar-molar region and has multilocular appearance.
- *Ameloblastic fibro-odontoma*—it is multilocular and radiopacities of enamel and dentin are seen inside the radiolucency as compared to adenomatoid odontogenic tumor where snowflakes are seen at the periphery.

Management

- *Exploration and enucleation*—AOC is treated by direct exploration and enucleation.
- *Marsupialization*—in some cases when lesion is associated with impacted tooth, marsupialization is done for eruption of tooth.

Lateral Periodontal Cyst

The lateral periodontal cyst is uncommon but a well recognized type of developmental odontogenic cyst. The designation lateral periodontal cyst is confined to that cyst,

which occurs as a result of inflammatory etiology and the diagnosis of collateral keratocyst has been excluded on clinical and histological ground.

Pathogenesis and Etiology

- *From dentigerous cyst*—initially origin is thought to be arising from dentigerous cyst which develops along the lateral surface of the crown. As the tooth erupts the cyst assumes a position in approximation to the lateral surface of the root.
- *Proliferation of cell rests of Malassez*—proliferation of cell rests of Malassez in the periodontal ligament may lead to lateral periodontal cyst. But stimulus which causes this proliferation is unknown.
- *Rests of dental lamina*—origin from proliferation and cystic transformation of rests of dental lamina (which is in post-functional state and therefore has only limited growth potential), that is in accordance with the usual small size of the cyst.
- *Post-functional dental lamina rests*—recent theory suggests that the lateral periodontal cyst and gingival cyst of adult share the common histogenesis from post-functional dental lamina rests. These two cysts represent basically the central or intra-osseous and peripheral or extra-osseous manifestations of the same lesion.

Types

- *Inflammatory*—it occurs near alveolar crest. Pocket content may irritate and stimulate rest of Malassez.
- *Developmental*—it is associated with developing tooth germ.

Clinical Features

- *Age and sex distribution*—the lateral periodontal cyst occurs chiefly in adults with an age range from 22 to 85 years with a mean age of 50 years. It shows a male predilection for occurrence.
- *Site*—the most frequent location of lateral periodontal cyst reported on lateral surface of the roots of vital teeth in mandibular canine and premolar region (**Fig. 13-22**) and is followed by the anterior region of the maxilla.
- *Symptoms*—gingival swelling may occur on the facial aspect and in such cases, it must be differentiated from the gingival cyst. In gingival cyst, the overlying mucosa is blue but in lateral periodontal cyst the overlying mucosa appears normal. When the cyst is located on the labial surface of the root, it appears as a slight obvious mass, overlying the mucosa.
- *Tooth*—the associated tooth is vital.
- *Infected cyst*—if the cyst becomes infected, it may resemble a lateral periodontal abscess.

Fig. 13-22: Ovoid radiolucency seen between roots suggestive of lateral periodontal cyst.

Radiographic Features

- **Shape**—the intra-bony lateral periodontal cyst is seen as a round or ovoid well defined radiolucency with hyperostotic borders.
- **Site**—it is usually found between the cervical margins and the apex of adjacent root surfaces and may or may not be in contact with root surfaces.
- **Size**—most of them are less than 1 cm in diameter except the botryoid variety which may larger and multilocular.

Variation of Lateral Periodontal Cyst

- **Botryoid odontogenic cyst**—this term was proposed by Waldron, which refers to a multilocular periodontal cyst. It resembles a cluster of lateral periodontal cysts exhibiting some difference. The lesion is multilocular with thin fibrous connective tissue septa. It is clear from numerous reports of recurrence that the botryoid odontogenic cyst requires careful excision.

Diagnosis

- **Clinical diagnosis**—normal color swelling seen in canine region.
- **Radiological features**—ovoid shaped radiolucency seen between roots of teeth with hyperostotic borders.
- **Laboratory diagnosis**—it is lined by a layer of stratified squamous epithelium with connective tissue wall. Cuboidal and columnar cells may be found compassing the lining. The lumen of the cyst shows focal thickened plaque of proliferating lining cell. These are especially prominent in botryoid cyst.

Differential Diagnosis

- **Lateral radicular cyst**—In radicular cyst, the lamina dura will not be intact and it is associated with pulpal infection and a non-vital tooth.
- **Lateral periodontal abscess**—it is very difficult to differentiate between abscess and cyst, but if it is less than 1.5 cm then it is considered as an abscess.
- **Lateral dentigerous cyst**—it is generally associated with an impacted tooth i.e. third molars and canines.
- **Residual cyst arising from the primary or permanent dentition**—there will be a history of extraction of the tooth.
- **Primordial cyst**—if primordial cyst arising from supernumerary tooth is superimposed on adjacent root surface, then it may be considered in differential diagnosis of lateral periodontal cyst. However, primordial cyst is more common at a younger age. So, to confirm the diagnosis of primordial cyst, radiographic examination from a different angulation should be carried out.
- **Globulomaxillary cyst**—it is seen in between maxillary lateral incisor and canine region common in young age and appears as a pear shaped radiolucency.
- **Median mandibular cyst**—it occurs in the midline of mandible.

Management

- The lateral periodontal cyst must be surgically removed if possible without extracting the associated tooth. If this cannot be accomplished, the tooth must be sacrificed. There is a tendency for recurrence for this type of cysts following its surgical excision.

Gingival Cyst of Adult

It is an uncommon cyst occurring either on free or attached gingiva. It is considered as soft tissue counterpart of lateral periodontal cyst.

Etiology and Pathogenesis

- **Proliferative epithelial tissue**—degenerative changes in proliferating epithelial tissue can occur which will result in gingival cyst of adults.
- **Remnants of dental lamina and enamel organ**—remnants of dental lamina, enamel organ or epithelial islands of periodontal membrane.
- **Trauma**—traumatic implantation of epithelium.
- **Post-functional rest of dental lamina**—it can also arise from post-functional rests of dental lamina.

Clinical Features

- **Age**—the gingival cyst may occur at any age, but it is most common in adults in the 5th and 6th decade of life.

- **Site**—the location of the lesion closely follows that of lateral periodontal cyst. It is more common in mandibular premolar and canine region with predilection for males.
- **Symptoms**—it is slowly enlarging, painless swelling, usually less than 1 cm in diameter and may occur in attached gingiva or the interdental papilla.
- **Appearance**—the surface may be smooth and the color may appear as that of normal gingiva or bluish (Fig. 13-23) and may appear red when it is blood filled as a result of recent trauma. Swelling is dome shaped.
- **Signs**—the lesions are soft and fluctuant and adjacent teeth are usually vital during surgical exploration.

Fig. 13-23: Bluish color swelling seen in premolar region due to gingival cyst of adults.

Radiographic Features

- **Superficial bone erosion**—there may be no radiological changes or only a faint round shadow indicative of superficial bone erosion (Fig. 13-24).

Fig. 13-24: Same patient (Fig. 13-23) showing slight erosion of underlying bone (Courtesy Dr Soni).

Diagnosis

- **Clinical diagnosis**—bluish color swelling of gingiva which is dome shaped will suspect gingival cyst of adults.
- **Radiological features**—bone erosion can be present.
- **Laboratory diagnosis**—biopsy has similar feature as that of lateral periodontal cyst.

Difference between Lateral Periodontal Cyst and Gingival Cyst of Adults

Although, it has been customary to consider these cysts as a distinctly different entity, their clinical appearance and behavior, morphologic and histochemical features and site of occurrence are so similar in appearance that they are in reality the intraosseous and extraosseous manifestations of the same pathosis. Bhaskar grouped the gingival and lateral periodontal cysts together as gingival cyst and considered that they both arise from extra-osseous odontogenic epithelium.

- **Location**—lateral periodontal cyst arises in the periodontium and located in the interproximal bone between the apex and the alveolar crest. Gingival cyst appears as a dome shaped swelling in the attached gingiva.
- **Radiological finding**—there is circumscribed radiolucency which occurs due to cup shaped depressions on the periosteal surface of cortical plates produced by enlargement of the gingival cysts. In case of lateral periodontal cyst there is round shaped radiolucency. The gingival cyst may certainly occur without bone involvement and may produce a gingival swelling. Most of the times, the swelling goes unnoticed. It is improbable though not impossible that a cyst originating in the gingival soft tissue could enlarge sufficiently to produce radiolucency by obvious bone erosion without producing any gingival swelling. In the case of a lesion, which has produced both gingival swelling and radiolucency, faint shadow (due to surface depression) indicates gingival cyst. Where the radiolucency is dark and sharply demarcated and a communication with the periodontium is indicated then the lesion is more likely to be lateral periodontal cyst that has eroded outward. These assumptions are based on radiological features and can be confirmed by surgical exploration when the lesion is being removed.

Management

- **Surgical excision**—surgical excision of the lesion in adults is usually recommended and the lesion does not tend to recur. A neoplastic potential has never been reported.

Palatal Cyst of Newborn (Epstein's Pearls, Bohn's Nodules)

Developmental cysts are common in newborn infant.

Pathogenesis

- *Entrapment of epithelium*—during the formation of secondary palate, small island of epithelium is entrapped below the surface along the median palatal raphe. Epithelium may be derived from minor salivary gland of palate.
- *Epstein's pearls*—these are cystic keratin filled nodules found along the midpalatine raphe probably derived from entrapped epithelial remnants along the line of fusion.
- *Bohn's nodules*—these are keratin filled cyst scattered over the palate most numerous along the junction of hard and soft palate and apparently derived from palatal salivary gland structure. The nodules are considered as remnants of mucus gland and are histologically different from Epstein's pearls.

Clinical Features

- *Appearance*—it is white or yellowish papule seen along the midline of palate.
- *Location*—it is present at junction of hard and soft palate.
- *Size*—it is usually 1 to 3 mm in diameter. Sometimes it may form clusters.

Management

- No treatment is required and cyst ruptures onto mucosal surface and eliminate their keratin content.

Dental Lamina Cyst

The cyst is apparently originated from remnants of dental lamina. They are multiple, occasionally solitary nodule on the alveolar ridge of newborn originating from remnants of the dental lamina (Fig. 13-25).

Clinical Features

- *Age*—these cysts are rarely seen after 3 months of age.
- *Site*—it is found on the crest of the maxillary and mandibular dental ridges.
- *Appearance*—clinically it appears as small whitish projection on the alveolar ridge of the jaws of infants giving mistaken appearance of a tooth (Fig. 13-26) at times appearing blanched due to internal pressure.
- *Size*—it is raised nodules, usually multiple, measuring a fraction of a millimeter to 2-3 mm in diameter.

Fig. 13-25: Dental lamina cyst showing elevation on alveolar ridge (Courtesy Dr Bhaskar Patle).

Fig. 13-26: Dental lamina cyst giving appearance of raised nodule on alveolar ridge (Courtesy Dr Bhaskar Patle).

Diagnosis

- *Clinical diagnosis*—whitish soft tissue elevation on alveolar ridge in infant will diagnose this condition.
- *Laboratory diagnosis*—there is thin epithelial lining and shows lumen filled with desquamated keratin, occasionally containing inflammatory cells.

Management

- No treatment is required as these lesions almost invariably disappear by rupturing onto the surface of the mucosa or through disruption by erupting teeth.

Calcifying Epithelium Odontogenic Cyst (CEOC)

It is also called as 'keratinizing and calcifying odontogenic cyst, dentinogenic ghost cell tumor, calcifying ghost cell odontogenic cyst' and 'Gorlin's cyst' as it was first described by Gorlin in 1962. The lesion is unusual in that it has some

features suggestive of cyst but also has many characteristic of a solid neoplasm.

Types

Clinical

- *Central or intraosseous variety*—it is also called as intraosseous odontogenic cyst. Cyst occurs centrally within the bone.
- *Peripheral or extraosseous variety*—it may occur peripherally in the soft tissue overlying the tooth bearing area.
- *Associated with odontogenic tumor*—this variety associated with odontogenic tumor.

Prattorius

He divided this variety into three types:

- Simple unicystic type.
- Unicystic odontome producing type.
- Unicystic ameloblastomatous proliferating type.

Clinical Features

- *Age and sex distribution*—most of the cases are diagnosed in 2nd and 3rd decade of life. It is slightly more prevalent in women.
- *Site*—3/4th of the lesions occur centrally, with about equal in both jaws and 75% occurring anterior to the first molar.
- *Symptoms*—it is slow growing, painless, non-tender swelling of the jaws. Occasionally, some patients may complain of pain.
- *Signs*—in some cases, cortical plate over the expanding lesion may be destroyed and cystic mass may be palpable with patients reporting of discharge. Aspiration yields viscous, granular, yellow fluid.
- *Teeth*—adjacent teeth may be displaced.

Radiographic Features

- *Radiodensity*—the central lesion may appear as a cyst like radiolucency.
- *Margins*—it presents with variable margins which may be quite smooth with a well defined outline or irregular in shape with poorly defined borders.
- *Teeth*—it is not unusual to find these associated with unerupted teeth and in some cases as pericoronal radiolucency. Roots of adjacent teeth may show resorption.
- *Internal structure*—it may contain small foci of calcified material that are only microscopically apparent. In some cases, it is completely radiolucent while in other cases an increasing amount of calcified material may be seen as white flecks. It may be unilocular or multilocular. In some cases, calcified material may occupy most of the lesions.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological features*—cystic lesion with calcification seen inside the bony cavity (**Fig. 13-27**) may give clue to the diagnosis.
- *Laboratory diagnosis*—focal areas of stellate reticulum and ghost cell may be present as well as sparse amount of dentinoids may be seen. Ghost cells are pale eosinophilic swollen epithelial cells that have lost its nucleus and nuclear membrane.

Fig. 13-27: Calcifying epithelial odontogenic cyst showing some degree of calcification.

Differential Diagnosis

- *Fibrous dysplasia (initial stage)*—it appears as mottled or smoky defined border on radiographs. It has poorly defined borders. It is more common in the maxilla.
- *Partially calcified odontoma*—it appears within the capsule.
- *Adenomatoid odontogenic tumor (AOT)*—in intermediate stage of development of AOT, radiographically it appears like CEOC.
- *Ossifying fibroma (initial stage)*—the fibro osseous lesions are likely to be situated in more inferior position in the mandible. It may show root resorption. Histologically, it shows 'Chinese letter' shaped islands of bone or calcification distributed throughout the connective tissue.
- *Odontogenic fibroma*—histologically, it shows odontogenic tissue like cementum.
- *Cementoblastoma*—the radiographic image is well defined and attached to the root of tooth.

Management

- *Surgery*—enucleation and curettage should be done.

Glandular Odontogenic Cyst

It is also called as '*Sialo odontogenic cyst*', or '*mucoepidermoid cyst*'. It is developmental odontogenic cyst which also shows salivary or glandular features.

The most descriptive term of the lesion is probably mucoepidermoid odontogenic cyst because of the presence

of both secretory elements and stratified squamous epithelium.

Clinical Features

- *Age*—it is more commonly occur in middle aged adults.
- *Site*—it is more commonly seen in mandible with slight predilection for anterior region.
- *Size*—size is usually less than 1 cm in diameter.
- *Symptoms*—small lesions are asymptomatic but large lesions may associate with pain and paresthesia.
- *Sign*—expansion may be present in large lesion.

Radiological Features

- *Appearance*—it is a unilocular or multilocular radiolucency with either smooth or scalloped margins (**Fig. 13-28**).
- *Margin*—margin of the lesion is well defined with sclerotic margin.

Fig. 13-28: Glandular odontogenic cyst present with scalloped margin in posterior region of mandible.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological features*—multilocular appearance with scalloped margin may suspect this cyst.
- *Laboratory diagnosis*—histologically, it shows cystic space lined by non-keratinized epithelium. The mucus and cylindrical cells form an integral part of the epithelial component with mucinous material within the cystic space.

Management

- *Surgery*—enucleation or curettage should be performed in this case. Recurrence is common in this type of cyst.

Inflammatory Cysts

Radicular Cyst

It is also called as 'apical periodontal cyst', 'periapical cyst', or 'dental root end cyst'. It is a common sequelae in progressive

changes associated with bacterial invasion and death of the dental pulp. It most commonly occurs at the apices of teeth.

The radicular cyst is classified as an inflammatory cyst because this process is thought to initiate the growth of the epithelial component.

Pathogenesis and Origin

- *Periradicular inflammatory changes*—periradicular inflammatory changes cause the epithelium to proliferate. As the epithelium grows into a mass of cells, the center loses the source of nutrition from the periapical tissue. These changes produce necrosis in the center and a cavity is formed and cyst is created.
- *Abscess cavity formation*—another theory is that an abscess cavity is formed in the connective tissue and is lined with proliferating epithelial tissue.
- *Origin of epithelium*—origin of cyst may occur from cell rests of Malassez which are remnants of Hertwig's root sheath and is a product of the odontogenic epithelial layer.
- *Other sources of epithelium origin*—the epithelium may be derived in some cases from respiratory epithelium of the maxillary sinus, when the periapical lesion communicates with the sinus wall, oral epithelium proliferates apically from the periodontal pocket and oral epithelium forms a fistulous tract.

Clinical Features

- *Age*—peak frequency occurs in the 3rd decade and there are large numbers of cases in the 4th and 5th decades after which there is a gradual decline. Although dental caries is more common in deciduous teeth in the first decade but radicular cysts are not often found in deciduous teeth may be because teeth tend to drain more readily than the permanent teeth and the antigenic stimuli which evoke the changes leading to the formation of radicular cyst may be different.
- *Sex*—male predominance, as females are less likely to neglect their maxillary anterior teeth and males are more likely to sustain trauma to their maxillary teeth. It shows a higher frequency of occurrence in whites.
- *Site*—maxillary anterior are more commonly affected. Also in addition to caries, maxillary teeth are more prone to traumatic injuries which lead to pulp death.
- *Symptoms*—it represents an asymptomatic phase in periapical inflammatory process following death of the dental pulp. It is associated with non-vital tooth (**Fig. 13-30**).
- *Signs*—it rarely causes non-tender expansion of the overlying cortical bone. Intraoral and extraoral swelling may be visible in some cases (**Fig. 13-29**).

Fig. 13-29: Radicular cyst involving upper premolar region showing extraoral swelling (Courtesy Dr Bhaskar Patle).

Fig. 13-30: Intraoral swelling in association with non-vital central incisor in case of radicular cyst (Courtesy Dr Bande).

- **Teeth**—the associated tooth is not sensitive to percussion.
- **Consistency**—swelling may be bony hard or crepitations may be present as bone is thinned or it may be rubbery or fluctuate, if the bone is completely destroyed.
- **Complication**—ameloblastoma, epidermoid carcinoma and mucoepidermoid carcinoma may arise in the epithelial lining of periapical cyst.

Radiographic Features

- **Shape**—it appears as a rounded or pear shaped radiolucency at the apex of non-sensitive tooth or with non-vital tooth (**Fig. 13-31**).
- **Site**—it appears on the mesial or distal surface of a tooth root, at the opening of an accessory canal or infrequently

Fig. 13-31: Radicular cyst, occlusal view seen as pear shaped radiolucency.

in a deep periodontal pocket. In some cases, radicular cyst can be associated with deciduous teeth (**Fig. 13-32**).

- **Size**—radiolucency is more than 1.5 cms in diameter but usually less than 3 cms in diameter. It has got well-defined outline with thin hyperostotic borders.

Fig. 13-32: Radicular cyst associated with deciduous teeth.

- **Margins**—in uncomplicated cases, margins are smooth, corticated and the cortex is usually well defined, well etched and continuous, except in some cases, where, there may be window formation. There is also thin white line surrounding the margins of the bone cavity. This thin layer of cortical bone is almost always present unless suppuration supervenes in the cyst.
- **Resorption of root**—radicular cysts of long duration may cause resorption of roots.
- **Adjacent teeth**—adjacent teeth are usually displaced and rarely resorbed (**Figs 13-34 and 13-35**).
- **Maxillary antrum**—if it involves maxillary area then displacement of antrum can occur. Due to distal inclination of the root (**Fig. 13-33**), cyst which arises from lateral incisor may invaginate the antrum.
- **Cortical plate**—the outer cortical plates of the maxilla or mandible may expand in a curved or circular shape.

Fig. 13-33: Radicular cyst present in the maxillary anterior region.

Fig. 13-34: Radicular cyst causing displacement of anterior teeth.

Fig. 13-35: Radicular cyst seen associated with two teeth.

- *Alveolar nerve canal*—cyst may displace the mandibular alveolar nerve canal in inferior direction.
- *CT finding*—CT image shows expansive process with sclerotic border.
- *MRI finding*—T1 weighted image shows oval expansive process with homogenous high signal. There may be rim enhancement.

Diagnosis

- *Clinical diagnosis*—swelling associated with non-vital teeth may give clue to the diagnosis.
- *Radiological diagnosis*—well defined radiolucency with size more than 1.5 cm is associated with non-vital teeth with loss of lamina dura will confirm the diagnosis of radicular cyst.
- *Laboratory diagnosis*—cyst is lined by stratified squamous epithelium. Hyaline bodies or Rushton bodies often found in great numbers in the epithelium of apical periodontal cyst. Collection of cholesterol cleft with associated multinucleated giant cells is found in the wall of the lesion.

Differential Diagnosis

- *Periapical granuloma*—if the radiolucency is smaller than 1.5 cm then it is most likely to be a granuloma. Cysts show a straw colored fluid on aspiration. Cyst is more apt to have thin hyperostotic borders than granuloma. Morse and coworkers described chair side method for differentiating cysts and granuloma. This method involves the use of alkaline copper tartarate in cystic fluid aspirate. A consistent color difference related to difference in protein content was observed for cyst and granuloma. Aspirate of root canal fluid from patients with cyst showed an intense albumin pattern and definite pattern in globular zones on polyacrylamide gel electrophoresis and fluid associated with periapical granuloma on the other hand shows only a faint-to-moderate pattern in the albumin zone.
- *Periapical scar*—it can be eliminated on the basis of history and location.
- *Surgical defect*—it can be diagnosed on the basis of history.
- *Lateral periodontal cyst*—radicular cyst originates from maxillary lateral incisor and positioned between the roots of the lateral incisor and canine and may get confused with lateral periodontal cyst. In such case, vitality of the tooth should be checked. Tooth in relation with the lateral periodontal cyst is vital and with the radicular cyst it is non-vital.
- *Periapical cementoma (early stages)*—in cementoma, the tooth is vital whereas the tooth with granuloma or cyst has a non-vital pulp. Periapical cementoma mostly involves the incisors.

- *Traumatic bone cyst*—the pulp of associated tooth is usually vital. 90% of traumatic cysts occur in mandible, i.e. in molar and premolar area whereas the periapical cyst has no predilection for occurrence.
- *Periodontal abscess*—it usually shows moderate to severe crestal bone loss. Mostly the tooth is vital.
- *Mandibular infected buccal cyst*—it is more common in young patients. First molar is frequently involved. Pulp is usually vital. The lamina dura around the tooth is intact.
- *Benign tumor*—presence of septum inside the cavity is suggestive of benign tumor.

Management

- *Root canal treatment*—it is the treatment of choice as in many cases, radicular cyst resolve after root canal treatment. The reason behind it is that as drainage is established, the inflammatory process subsides and the fibroblast start producing collagen. The pressure of proliferating collagen reduces the blood supply to the epithelium lining and causes it to degenerate. Macrophages remove the degenerating epithelial tissue.
- *Extraction*—if the lesion fails to resolve, extraction of associated tooth is carried out.
- *Enucleation and marsupialization*—enucleation or marsupialization of a larger lesion is done.

Residual Cyst

It is a cyst that either remained as such in the jaw when its associated tooth was removed or was formed in residual epithelium of cell rests from a periodontal ligament of the lost tooth. Low grade inflammation of parent cyst might predispose formation of residual cyst.

Clinical Features

- *Age and sex*—cyst is common in patients older than 20 years with an average age of about 52 years. It is twice more common in male than female.
- *Site*—higher incidence in the maxilla. Mostly found on alveolar process (**Fig. 13-36**) or body of the tooth bearing area with some cysts described in the lower ramus of the mandible.
- *Symptoms*—it is asymptomatic with a previous history of pain in the tooth.
- *Size*—it is seldom more than 5 to 10 mm in diameter.

Radiographic Appearance

- *Pre-extraction radiograph*—pre-extraction radiographs show tooth with an evidence of deep caries or fractured tooth adequate for pulp involvement and/or an associated cyst.

Fig. 13-36: Swelling seen on alveolar ridge due to residual cyst (Courtesy Dr Tapasya Karamore).

- *Shape*—it is round or ovoid radiolucency that is usually well circumscribed (**Fig. 13-37**).
- *Margins*—thin radio-opaque margins are common with unilocular appearance although the infected cyst will not have such well defined margins.
- *Appearance*—due to resistance, cyst enlarges in elliptical shape with hyperostotic borders resulting from minimal pressure of expanding cyst.

Fig. 13-37: Residual cyst seen as well defined radiolucency (Courtesy Dr Tapasya Karamore).

Differential Diagnosis

- *Primordial cyst*—in it, tooth is missing without a history of extraction. It is more common in mandibular posterior teeth and at a younger age. On aspiration, it shows straw colored fluid.
- *Keratocyst*—it is more common in mandibular posterior area and at an early age. It may appear multilocular. The size of the cyst is larger when compared to residual cyst.

- *Traumatic cyst*—usually in the mandible, in apical region (if it is associated with tooth) it shows scalloped outline. It is common at younger age. Aspiration is non-productive.
- *Ameloblastoma* (in initial stages/unilocular)—usually the lesion appears larger compared to the residual cyst. There is no history of extraction of the tooth.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—well defined radiolucency with previous history of endodontic treatment and pre-extraction radiograph showing radiolucency.

Management

- *Enucleation*—If the cyst is not large and patient's age and health will tolerate the insult, the cyst wall should be completely enucleated. The extent of repair of the defect will depend on the size of the cyst and health of the patient.
- *Marsupialization*—in cases where the surgical procedure must be as atraumatic as possible, marsupialization or decompression may be used.
- *Excision*—complete excision and replacement with autogenously bone graft or single segment of bone fixed in it.

Inflammatory Collateral Cysts

They arise in the periodontium on the lateral aspect of an erupted tooth as a result of inflammatory process in the periodontal pocket. They arise by proliferation of cell rests of Malassez in the lateral periodontium. They are rare as drainage occurs more readily from the lateral periodontium which is closely associated with gingival crevice.

Paradental Cyst

It was first described by Craig in 1976. It is a cyst of inflammatory origin occurring on the lateral aspect of the root of partially erupted mandibular third molar with an associated history of pericoronitis.

Origin

- *Cell rests of Malassez*—it can be the origin, but argument is that if rests of Malassez were responsible then the lesion should be equally distributed around the root surface.
- *Reduced enamel epithelium*—second theory is that it originates from the reduced enamel epithelium as the presence of reduced enamel epithelium over the enamel projection might be the source and could explain the common location of the cyst.

Clinical Features

- *Age and sex*—it occurs between 10 to 39 years of age. It is most common in the third decade of life. It shows predilection for males.
- *Site*—usually associated with the third molar on the buccal surface (**Fig. 13-38**) and covers the bifurcation. It may occur bilaterally.
- *Signs*—the involved tooth is vital.

Fig. 13-38: Radiolucency seen distal to third molar in case of paradental cyst.

Radiographic Features

- *Radiodensity*—there is well demarcated radiolucency occurring distal to the partially erupted tooth but there was often buccal superimposition.
- *Intact periodontal ligament space*—the radiolucency sometimes extends apically but an intact periodontal ligament space provided the evidence that the lesion did not originate at the apex.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Radiological features*—radiolucency distal to third molar with intact periodontal ligament space.
- *Laboratory diagnosis*—cyst is lined by proliferating, non-keratinized squamous epithelium of varying thickness. The fibrous capsule is the seat of an intense chronic or mixed inflammatory cell infiltrate.

Management

- *Enucleation*—the lesion is treated by surgical enucleation.

Mandibular Buccal Infected Cyst or Buccal Bifurcation Cyst

It is an inflammatory cyst occurring on the buccal surface of mandibular molars in young children. The reason for

occurrence of this cyst is that inflammation response may occur in surrounding follicular tissue which stimulated cyst formation.

Clinical Features

- **Age**—a younger age group than the paradental cyst.
- **Site**—it affects the mandibular first and second molars more commonly rather than the wisdom teeth. The cyst is always situated on the buccal surface of the mandibular molar most frequently the first permanent molar after their partial or complete eruption (**Fig. 13-39**).
- **Symptoms**—there may be discomfort, pain, tenderness and rarely suppuration. Swelling, particularly if inflamed, is the clinical feature most likely to induce the patient to seek advice. Facial swelling may follow and this may be inflamed.
- **Signs**—pulp is vital in this cyst.
- **Teeth**—the associated tooth is usually tilted, so that the apices are adjacent to the lingual cortex, a feature of which is demonstrable in occlusal radiographs.
- **Size**—the size of cyst varies and may extend beyond the limit of the involved tooth and impinge upon and displace the crypt of the adjacent unerupted tooth.
- **Expansion**—the cyst extension in buccal direction is variable, but frequently the outer bony cortex is lost.
- **Pocket**—periodontal probing will show pocket formation on buccal side of first molar.

Fig. 13-39: Radiolucency associated with mandibular first molar with extension upto premolar with buccal expansion suggestive of buccal bifurcation cyst (*Courtesy Dr Parate*).

Radiographic Features

- **Periosteum**—with involvement of the periosteum, new bone may be laid down either as a single linear band or

laminated, if there are two or more layers. Sometimes, the new bone may be homogeneous.

- **Site**—the cysts will appear on the buccal aspects of the affected molars.
- **Bone**—usually there is involvement of the bone in the furcation and the entire interradicular bone may be lost.
- **Margins**—the inferior margins of the cyst is concave and rarely, the cyst may extend to the inferior border of the mandible but not leading to any external deformity.

Diagnosis

- **Clinical diagnosis**—the diagnostic features are the young age of the patient, the mandibular molar sites, buccal periostitis, usually vital pulp.
- **Radiological features**—intact lamina dura with buccal expansion visible on radiograph.
- **Laboratory diagnosis**—not so specific.

Management

- **Enucleation**—it is generally agreed that enucleation of the cyst without removal of the associated tooth is the treatment of choice.

Suppurating Cyst

When pyogenic organisms are present in sufficient number to produce changes, suppuration results. The thin white line which represents the cortex of the cyst becomes less dense and thinner and may be entirely lost (**Fig. 13-40**). In rare cases there is slight irregularity of the walls of the cyst, with some decalcification extending into the bone to a short distance. In the place of thin white cortex, there is sometimes a broad band of sclerosed bone which is less dense but wider than a normal cortex and presents a granular appearance.

Fig. 13-40: Loss of thin line of cyst due to suppuration on left side of radicular cyst in molar area (*Courtesy Dr Tapasya Karamore*).

Healing Cyst

A cyst that is caused by an infected tooth often heals after removal of that tooth. One of earliest change is the gradual loss of the cortical layer of bone which lines most of the

cysts. At the same time, if the cyst becomes infected, the bone in the immediate vicinity of the walls becomes radiolucent as a result of hyperemia.

After the period of time, there is gradual lessening of radiolucency of the cavity and a return of the surrounding bone to a normal density (Fig. 13-41). The dark shadow of the cavity is replaced by a grey one and it is apparent that the cavity is becoming smaller. A large cyst may fail to heal completely, resulting in a smaller cyst. This is due to the retention of some part of the epithelial wall of the cyst, which has continued its activity.

Fig. 13-41: Cyst is in healing stage. Note increased density of the bone in the mandibular right ramus region.

Non-odontogenic Cysts

Nasopalatine Cyst

It is also called as 'nasopalatine duct cyst', 'incisive canal cyst', 'median anterior maxillary cyst' or 'vestigial cyst'. It is the most common non-odontogenic cyst in the oral cavity. It is generally agreed that the nasopalatine duct cyst is an entity. It may occur within the nasopalatine canal or in the soft tissue at the opening of the canal where it is called as *cyst of the palatine papilla*. They are found to form in the canal or at the oral terminus of the canal.

Etiopathogenesis

- **Development**—it is developmental in origin and arises in the incisive canal when embryonic epithelial remnants of the nasopalatine duct undergo proliferation and cystic transformation. Some workers believe that it is derived from the epithelium included in the lines of fusion of embryonic facial processes.
- **Trauma**—in the form of direct blow to the incisive canal or indirectly from mastication, particularly when ill-fitting dentures are involved, have been suggested. But if this is true, the cyst would likely to be found more often and there would not be a male predilection.
- **Bacterial infection**—either from the nasal cavity or from the oral cavity, stimulates to the epithelial remnants to proliferate has been suggested as a cause. However, since

an open connection with the oral cavity or the nasal cavity is extremely rare, an evidence for the bacteria is lacking.

- **Retention phenomenon**—blocked duct of mucus glands causes an accumulation of secretion would be responsible for the cystic expansion.

Clinical Features

- **Age and sex distribution**—most cases discovered in the 4th and 6th decades and it is also frequently found in edentulous patients. It is three times higher in males than in females and found equally in blacks and whites.
- **Onset**—there is a small well defined swelling just posterior to the palatine papilla.
- **Pain**—sometime it may become infected, producing pain. Burning sensation and numbness may be experienced due to pressure on the nasopalatine nerve.
- **Salty taste**—patients complain of salty taste in mouth produced by small sinus or remnant of nasopalatine duct that permits cystic fluid to drain into oral cavity.
- **Fluctuant**—swelling is fluctuant and bluish if it is near the surface.
- **Palpation**—it is opened by a tiny fistula on or near the palatine papilla. In such cases, a tiny drop of watery fluid or pus may be elicited by pressure in this area.
- **Surface**—deeper cysts are covered by normal mucosa, unless it is ulcerated.
- **Expansion**—if cyst expands, it may penetrate the labial plate and produce a swelling below the maxillary labial frenum (Fig. 13-42).
- **Teeth**—roots of central incisors diverge. It may bulge into the nasal cavity and distort nasal septum.
- **Cyst of palatine papillae**—Sometimes, cyst formed in palatine papilla will be evident as an elevation or a soft round swelling of palatine papilla which extends posteriorly along the midline of the palate. It occurs anterior to the incisive foramen below the periosteum and do not enter invades the underlying bone.

Fig. 13-42: Nasopalatine duct cyst showing swelling in palate (Courtesy Dr Shetty).

- **Complication**—in some cases, it is reported that it may lead to malignancy of maxilla.

Radiological Features

- **Site**—typical cyst like radiolucency is superimposed with the apices of the central incisors. If cyst is formed in one of the branches of the canal, image will be displaced on one side of the midline.
- **Heart shape radiolucency**—image of radiopaque anterior nasal spine may superimpose over the dark cystic cavity giving it a heart shape (**Fig. 13-43**) or shape of inverted tear drop.
- **Shape**—in many cases, cyst is situated symmetrically in the midline. It may be rounded, oval or irregularly shaped.
- **Size**—size of the cyst is variable but usually from 6 mm to several centimeters in diameter.
- **Paired cyst**—two separated cysts may develop in two canals and cause paired cysts like radiolucency.
- **Erosion of bone**—cyst in canal cavity also erodes the bone posterior to the canal and creates impression of midpalatal cyst.
- **Teeth**—adjacent teeth usually show distal displacement but they are rarely resorbed. Divergence of central incisor roots and external root resorption is common.
- **Cyst of palatine papillae**—the cyst in the palatine papillae is not usually apparent because it does not cause enough pressure on the bone to cause discernible bone resorption but it can produce some bony erosions.

Fig. 13-43: Incisive canal cyst giving heart shaped radiolucency in incisor region.

Differential Diagnosis

- **Incisive fossa**—The shape of the fossa varies from round to oval to triangular to diamond to funnel shaped. Radiolucency in the area less than 6 mm wide should be considered as a normal fossa in the absence of associated

symptoms. Incisive fossa sharply defines at the lateral margins in contrast to the cyst, which has a well defined boundary on all margins. Aspiration will help to distinguish between cyst and incisive fossa.

- **Radicular cyst**—Pulp is non-vital with loss of lamina dura in the radicular cyst.
- **Dentigerous cyst with mesiodens**—Radiographic evidence of association with supernumerary teeth will establish the diagnosis of dentigerous cyst.
- **Median palatine cyst**—radiolucent lesion is behind the incisive canal in premolar-molar area.
- **Primordial cyst from supernumerary teeth**—more common in the posterior teeth.

Diagnosis

- **Clinical diagnosis**—swelling posterior to palatine papilla may give clue to the diagnosis
- **Radiological diagnosis**—heart shaped radiolucency in maxillary anterior region is typical of nasopalatine duct cyst.

Management

- **Surgical enucleation**—its removal is not indicated unless there are clinical symptoms. Removal is indicated in edentulous patients before dentures are introduced. Intraoral approach should be taken for the surgical enucleation.

Nasolabial Cyst

It is also called as 'nasopalveolar cyst' or 'Klestadt's cyst'. It is a soft tissue cyst, which involves the bone secondarily.

Pathogenesis

- **Fissural cyst**—some state that it is a fissural cyst arising from epithelial rests which are entrapped in the fusion lines of medial nasal, lateral nasal process and maxillary process.
- **Misplaced epithelium of nasolacrimal duct**—others state that it is actually a merging of mesenchymal processes and not a fusion per se, so there is no epithelial entrapment in the naso-optic fissure. They state that the location of nasopalveolar cyst strongly argues in favor of its development from the embryonic nasolacrimal duct that initially lies on the surface.

Clinical Features

- **Age and sex distribution**—it can occur at any age group with peak in 3rd and 4th decade of life. Women are more commonly affected in the ratio of 3:1.
- **Site**—it is unilateral but may be bilateral.

- **Symptoms**—it may cause pain and difficulty in breathing through the nose. There is swelling of the nasolabial fold and nose. In some cases, swelling may rupture spontaneously and it may drain into oral cavity.
- **Signs**—swelling is fluctuant on palpation. There is flaring of ala and distortion of nostril and fullness of upper lip below the nasal vestibule. It may bulge into the nasal cavity and cause some obstruction. Infection may drain into the nasal cavity.
- **Histopathological features**—it may contain goblet cells.

Radiographic Features

- **Site**—it is located above the apices of incisor in alveolar bone in maxillary region.
- **Radiodensity**—it is radiolucent lesion. Cyst causes an erosion of the underlying bone by virtue of its presence and pressure.
- **Margins**—usual outline of inferior border of nasal fossa is distorted resulting in posterior convergence of the margins.
- **Shape**—the actual shape and position of the cyst can be demonstrated by aspirating the typical cyst fluid and replacing it with radiocontrast material. A tangential view then demonstrates the *kidney shaped lesion* below the nasal fossa and above the apices of the incisors.

Differential Diagnosis

- **Acute dentoalveolar abscess**—in this case, tooth is tender on percussion. Radiographically, cystic radiolucencies are seen in case of nasoalveolar cyst.
- **Nasal furuncle**—no radiographic evidence of the lesion.
- **Mucus extravasation cyst**—no radiographic sign are seen.
- **Cystic salivary adenoma**—same as above.

Diagnosis

- **Clinical diagnosis**—difficulty in breathing from nose, flaring of ala of nose and distortion of nostril will diagnose nasolabial cyst.
- **Radiological diagnosis**—not specific.

Management

- **Intraoral surgical approach**—it should be excised using an intraoral approach. Some portion of nasal mucosa should also be removed for complete removal of cyst. There is no tendency to recur.
- **Endoscopic marsupialization**—in this case, transnasal approach is taken.

Anterior Alveolar Cyst

It is also called as '*median alveolar cyst*'. This cyst arises in the intermaxillary suture anterior to the site of anterior

palatine cyst. It arises near the labial surface of the premaxilla between the two incisors. There may be swelling at the site.

Radiologically, it occupies the position more close to the shadow of the crowns of the incisors than the root. It appears as area of radiolucency in the midline. The borders may be sharply defined or not. There may or may not be a thin layer of cortical bone at the periphery of the cavity. In some cases, when the cyst comes in contact, there is symmetrical resorption of the roots of teeth.

Nonepithelial Cysts

Idiopathic Bone Cavity

It is also known as '*solitary bone cyst*', '*hemorrhagic bone cyst*', '*extravasation cyst*', '*traumatic bone cyst*', '*simple bone cyst*', '*unicameral cyst*' and '*idiopathic bone*'. It is an unusual lesion which occurs with considerable frequency in the jaws as well as in other bones of the skeleton.

The traumatic bone cyst is a misnomer, since these intra-bony cavities are not lined by epithelium. It may results from trauma induced intra-medullary hematoma with subsequently result in bone resorption and cavitations during hematoma resolution.

Pathogenesis

- **Intramedullary hemorrhage**—it originates from intra-medullary hemorrhage following traumatic injury. Hemorrhage occurring within the medullary space of bone after trauma heals by organization of the clot and eventual formation of connective tissue and formation of new bone.
- **Traumatic injury theory**—according to the traumatic injury theory, however, it is suggested that after traumatic injury to an area of spongy bone containing hemopoietic marrow enclosed by layer of dense cortical bone, there is failure of organization of blood clot and for some unexplained reasons, subsequent degeneration of the clot that eventually produce an empty cavity within the bone.
- **Degeneration of clot**—in the development of the lesion, the trabeculae of bone in the involved area become necrotic after degeneration of the clot and bone marrow, although some viable marrow tissue must persist to initiate resorption of the involved trabeculae.
- **Infiltrating edema**—the lesion then appears to increase in size by steady expansion produced by a progressive infiltrating edema on the basis of restriction of venous drainage. This expansion tends to cease when the cyst-like lesion reaches the cortical layer of the bone, so that expansion of the involved bone is not a common finding in the solitary bone cyst.

- *Other causes of origin of cyst*—it may originate from bone tumors that have undergone cystic degeneration, as a result of faulty calcium metabolism such as that induced by parathyroid disease. It may originate from necrosis of faulty marrow due to ischemia, end result of low grade chronic infection and as a result of osteoclastic activity resulting from disturbed circulation caused by trauma thereby creating an unequal balance of osteoclastic activity and repair of bone.

Clinical Features

- *Age and sex*—the traumatic bone cyst occurs most frequently in young persons at an age of 6 to 20 years with a male predominance as they are exposed to traumatic injury most frequently than females with the ratio being 3:2.
- *Site*—it is usually found in mandible anywhere from the symphysis to the ramus, but about one-third are found in the maxilla, usually in the anterior region.
- *Symptoms*—it is asymptomatic in most cases but occasionally, there may be evidence of pain and tenderness.
- *Signs*—cortical swelling or slight tooth movement are not the usual finding and the teeth are vital.
- *Aspiration*—needle aspiration is actually unproductive and if it is productive, it contains either a small amount of straw colored fluid shed off necrotic blood clot and fragment of fibrous connective tissue.

Radiographic Features

- *Site*—they may be found in dentulous as well as edentulous arch.
- *Appearance*—it appears as a radiolucent lesion with a spectrum of well defined to moderately defined borders.
- *Margins*—most cases are unilocular with a fairly regular border. There is evidence of hyperostotic borders around the entire lesion but occasionally, such border is lacking. Most characteristic radiographic feature of this cyst is scalloped superior or occlusal margins where it extends between the roots of the teeth.
- *Size*—some cysts may be only a centimeter in diameter while others may be so large that they involve most of the molar area of the body of the mandible as well as part of the ramus.
- *Teeth*—they may be superimposed with the root or 'scallop' superiorly between the roots. Occasionally, lamina dura of the tooth may be absent and even less frequently the root may show resorption.
- *Alveolar bone*—it rarely causes cortical expansion but if it occurs, it is mostly buccal (**Fig. 13-44**). Surface is smooth, the cortical plates are not disrupted and pathological fracture does not result. The cavity occupies the position in the body of the jaw, but it may extend to involve the alveolar process.

Fig. 13-44: Idiopathic bone cavity with thinned cortex and expansion of bone (Courtesy Dr Tapasya Karamore).

Diagnosis

- *Clinical diagnosis*—it is very difficult to make clinical diagnosis.
- *Radiological diagnosis*—well defined radiolucency with vital tooth with history of trauma will give clue to diagnosis.
- *Laboratory diagnosis*—aspiration is non-productive. Biopsy shows fragments of fibrin with enmeshed red cells may be seen. Hemorrhage and hemosiderin fragments are usually present and scattered small cells are often found.

Differential Diagnosis

- *Radicular cyst*—in radicular cyst, tooth is usually non-vital. Further, all the true cysts tend to have a more rounded appearance.
- *Central giant cell granuloma*—it usually shows evidence of internal bony septa where traumatic bone generally lacks. It is more common in mandibular anterior region.
- *Ameloblastoma and odontogenic myxoma*—are usually multilocular.
- *Lesions of eosinophilic granuloma*—these lesions are not well corticated as that of traumatic bone cyst.
- *Fibrous dysplasia*—not so corticated.

Management

- *Surgical exploration*—simple surgical exploration to establish the diagnosis. When the correct diagnosis is determined, enucleation and curettage are carried out.
- *Intralesional steroid injection*—this can yield limited success in some cases of traumatic bone cyst.

Cysts of the Maxillary Sinus

It is discussed in Chapter 27: Disorders of Maxillary Sinus.

Cysts of Soft Tissues of the Face and Mouth

Epidermoid Cyst

Epidermoid cyst is a simple cyst which is filled with cyst fluid or keratin and no other specialized structure. Epidermoid cyst is lined by epidermis, but contains no appendages. Epidermoid cyst is also called as *infundibular cyst* as most of cysts are derived from follicular infundibulum.

Pathogenesis

- *Trauma*—implantation keratinizing epidermoid cyst may occur in other parts of the mouth as a result of trauma. This type of cyst is also called as *epidermal inclusion cyst*.
- *Infundibular epithelium*—there is non-neoplastic proliferation of infundibular epithelium from healing process of localized inflammation of hair follicle.

Clinical Features

- *Age and sex distribution*—it is more common in 2nd and 3rd decade of life. Males are more commonly affected as compared to female.
- *Location*—these are most common on head, neck, face and back of the patient.
- *Appearance*—it is nodular lesion (Fig. 13-45) which may be associated with inflammation.

Fig. 13-45: Epidermoid cyst showing nodular appearance on the face of patient (Courtesy Dr Bande).

- *Fluctuation test*—it is positive.
- *Syndrome associated*—it is associated with Gardner's syndrome.

Diagnosis

- *Clinical diagnosis*—nodular lesion on face with positive fluctuant test will give clue to the diagnosis.

Management

- *Conservative surgical excision*—it is treated by conservative surgical excision.

Dermoid Cyst

It may occur as developmental anomalies and about 1 to 2% occurs in oral cavity. It contains sebaceous material as well as keratin. If lumen contains elements such as bone, muscles or teeth from various germinal layer is called as '*teratoma*'. Dermoid cyst is benign cystic form of teratoma. Dermoid cyst is lined by epidermis and skin appendages are present in the fibrous wall.

Types

- *Median variety*
 - Supramylohyoid variety
 - Inframyllohyoid variety
- *Lateral variety*
 - Supramylohyoid variety
 - Inframyllohyoid variety

Clinical Features

- *Age and sex*—it occurs at any time from birth to adolescence and it is small in infancy and large in adolescence. Mainly, it is apparent between 12 to 25 years of age and occurrence is equal in both sexes.
- *Site*—midline of the floor of mouth is the commonest location of these cysts which may cause a swelling in the midline of the neck or sometimes, it may be lateral. On the face, it can be seen on the forehead (Fig. 13-46).
- *Symptoms*—swelling is slow and painless. In the case of supramylohyoid variety, swelling may displace the tongue and it may interfere with breathing, speaking, closing the mouth and eating.
- *Size*—the size may vary up to several centimeters in diameter.
- *Palpation*—swelling is soft to firm, rubbery or cheesy consistency and sharply delineated.
- *Aspiration*—it contains straw colored fluid.
- *Transillumination test*—it is usually negative.
- *Fluctuation test*—it is generally positive.
- *Color and surface*—if superficial, it is yellow to white and surface is smooth and non-ulcerated until traumatized.

Fig. 13-46: Dermoid cyst presenting as well defined swelling on the forehead of patient.

- *Movement with tongue*—it does not move with protrusion of the tongue or deglutition.
- *Double chin appearance*—inframylaryoid variety also causes swelling in the submental area which gives rise to a 'double chin' appearance.

Radiographic Appearance

- *CT scan*—CT scan may be useful for the detection of dermoid cyst.
- *Contrast study*—in some cases, if you want to see the extent of the cyst, then we have to remove some content of the cyst to enable introduction of an opaque substance such as lipiodol, which is chemical combination of iodine and poppy seed oil. After this, radiograph is made from every position necessary to enable opaque material find its way by gravity to each portion of the cyst.

Differential Diagnosis

- *Ranula*—it is not in midline and appears bluish. Transillumination test is positive.
- *Unilateral or bilateral blockage of Wharton's duct*—in this case patient experience pain during meals.
- *Thyroglossal duct cyst*—it lifts when the patient swallows or protrudes the tongue.
- *Cellulitis*—the swelling is diffuse and widespread.
- *Submandibular lymph nodes swelling*—it is solid.

Diagnosis

- *Clinical diagnosis*—midline location is typical feature of this disease.
- *Radiological diagnosis*—contrast study will diagnose this lesion.

Management

- *Surgical excision*—it is the treatment of choice. Supramylaryoid variety should be excised through intraoral approach and inframylaryoid variety should be excised taking extraoral approach.

Lymphoepithelial Cyst

Its location in the neck, parotid gland and other intraoral areas will be dealt separately. Lymphoepithelial cyst of neck is called as 'branchial cleft cyst'.

Pathogenesis

- *From cervical sinus*—caudal overgrowth of second arch covers the grooves of second, third and fourth branchial arch. These grooves lost contact with outside and from the ectoderm line cervical sinus. Failure of these cervical sinus results in formation of branchial cyst.
- *From glandular epithelium*—it may originate due to cystic transformation of glandular epithelium entrapped within the oral lymphoid aggregates during embryogenesis. Epithelium in lymphoepithelial cyst might be derived from the ductal epithelium of salivary glands.
- *Parotid gland lymphoepithelial cyst*—cystic changes occur in parotid gland epithelium which becomes entrapped in upper cervical lymph nodes during embryonic life.
- *Oral lymphoepithelial cyst*—lymphoid tissue is found in oral cavity in the area of palatine tonsil, lingual tonsil and pharyngeal adenoids. Lymphoid aggregates may also occur in the floor of mouth, ventral surface of tongue and soft palate.

Clinical Features

Lymphoepithelial cyst of the neck

- *Age*—occurs at all ages with a fairly equal distribution from first to sixth decade.
- *Site*—location is superficially in the neck, close to the angle of the mandible, anterior to the sternocleidomastoid muscle.
- *Size*—the neck lesions vary in size from small to very large (about 10 cm in diameter).
- *Symptoms*—there is swelling, which may be progressive or intermittent and pain may also be a feature.
- *Sign*—it is soft, fluctuant swelling. Some of the cyst may form mucoid discharge on to the skin through the opening.

Lymphoepithelial cyst of parotid gland

- *Age*—the age ranges from 16 to 69 years with a male to female ratio of 3:1.
- *Symptoms*—there is a nodule in the parotid gland.
- *Signs*—it is most commonly associated with HIV infection.

Oral lymphoepithelial cyst

- **Age**—the age range is 15-65 years with a male predominance.
- **Site**—it affects mainly the floor of mouth and the tongue.
- **Appearance**—the cyst appears as a non-ulcerated freely movable mass which has been present for a period ranging from 1 month to a year.
- **Symptoms**—patients may complain of swelling and discharge.
- **Size**—size may vary from few millimeters to 2 cm.
- **Signs**—fairly mobile, superficial soft fluctuant, sharply delineated swelling.
- **Shape and color**—the usual observation was of round or oval swelling of the oral mucosa of normal color but when large swelling they were yellow or white in color.

Management

- **Surgical excision**—surgical removal of the cyst should be carried out. There are no chances of recurrence.

Thyroglossal Duct Cyst

It is also called as 'thyroglossal tract cyst'. The analogue of the median lobe of the thyroid gland develops at about the fourth week of the intrauterine life from a site at the base of tongue which is recognized later as the foramen caecum. A hollow epithelial stalk known as the thyroglossal duct extends caudally and passes ventrally to the hyoid bone to the ventral aspect of the thyroid cartilage where it joins the developing lateral lobe. The thyroglossal duct disintegrates by about tenth week of intrauterine life, but cyst may form from residue of the duct at any point along its line of descent.

Pathogenesis

- **Origin**—it develops from remnant of thyroglossal duct.
- **Stimulation**—it is stimulated by inflammatory conditions which lead to reactive hyperplasia of the lymphoid tissue near remnant of thyroglossal duct.
- **Accumulation**—this reactive hyperplasia block the thyroglossal duct, resulting in accumulation of secretion and formation of cyst.

Clinical Features

- **Age and sex distribution**—it is slightly more common in women and occurs commonly in the first, second and third decades of life.
- **Site**—most commonly located in midline in the area of hyoid bone and when they occur in the mouth, they are either in the floor or at the foramen caecum.
- **Symptoms**—it is painless and movable swelling. Pain may occur if the cyst is infected. If they are located high in the tract, they may cause dyspnea.

- **Shape**—it is spherical or oval with a long axis along the thyroglossal tract.
- **Size**—the cyst varies in size from 0.5 to 5 cm in diameter.
- **Signs**—they lift when the patient swallows or protrudes the tongue. It is fluctuant and tender swelling. Consistency is often firm or hard depending upon the tension of fluid within the cyst.
- **Movement with deglutition**—cyst moves with deglutition as swelling is attached to hyoid bone by fibrous tissue. It also moves with protrusion of tongue.
- **Fluctuation and transillumination**—it is usually positive.
- **Complication**—complication like fistula formation, recurrent infection can occur.

Differential Diagnosis

- **Subhyoid bursal cyst**—it moves with deglutition but not with protrusion of tongue.
- **Sublingual dermoid**—it does not move with protrusion of the tongue.

Management

- **Sistrunk operation**—it involves the removal of a 1 cm block of tissue surrounding the duct and the duct should be traced down to the pyramidal lobe of thyroid gland and to the foramen caecum at the base of tongue.

Anterior Median Lingual Cyst

It is also called as 'intralingual cyst of foregut origin'. It is a rare lesion and is commonly found in children. It can be present since birth and recurrence is common. It is a fluctuant swelling in anterior half of the tongue. There may be difficulty in feeding.

Oral Cyst with Gastric or Intestinal Epithelium

It is also called as 'oral alimentary tract cyst'.

Pathogenesis

- **Location of primitive stomach**—Gorlin pointed out that in the 3-4 mm embryo, the undifferentiated primitive stomach lies in the mid-neck region, not far from analogue of the tongue. Gastric mucosa has been shown to occur in the esophagus of 7.8% of infant and in 51% of these, heterotrophic tissues were located in the upper third.
- **Fusion of endodermal and ectodermal epithelia**—it is suggested that in the sublingual region of the oral cavity and in the region of apex and dorsum of tongue, the ectodermal and endodermal epithelia fuse and this will explain presence of heterotrophic gastric or intestinal mucosa.

Clinical Features

- *Age and sex*—most cases occur in infants and young children between the ages of 2 to 11 years. The male to female ratio is 3:1.
- *Site*—common location is in the anterior part of the tongue, floor of mouth and submandibular gland. The cyst may be enclosed entirely within the tongue or floor of mouth or may communicate with the surface.
- *Appearance*—swelling may be seen in tongue.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Laboratory diagnosis*—the cyst may be lined partly by stratified squamous epithelium and partly by gastric or intestinal mucosa.

Management

- *Surgical excision*—surgical excision should be carried out. Recurrence is rare but has been reported.

Cystic Hygroma

It is a developmental abnormality in which there is progressive dilatation of lymphatic channels.

Clinical Features

- *Age*—it is often present at birth and most cases are diagnosed before the age of 2 years.
- *Site*—it frequently involves the neck and face, although it can occur anywhere in the body.
- *Symptoms*—those that involve facial tissue produce a swelling often painless and usually compressible.
- *Signs*—the overlying skin may be blue and the swelling transilluminates. There may be a history of gradual or sudden enlargement.

Diagnosis

- *Clinical diagnosis*—painless swelling present from birth with transillumination test positive will give clue to the diagnosis.
- *Laboratory diagnosis*—histologically, the cystic hygroma consists of dilated cystic spaces lined by endothelial cells.

Management

- *Surgical excision*—complete surgical removal of the mass.

Nasopharyngeal Cyst

They are rare clinical entities. They may be classified as congenital or acquired and in midline or lateral. They are

lined by ciliated or non-ciliated columnar epithelium with areas of squamous metaplasia in response to inflammatory stimuli. Lymphoid follicles are present in the wall.

Congenital midline cyst arises either from the pharyngeal bursa or from Rathke's pouch. Cysts arising from Rathke's pouch are exceedingly rare. They have a median base attached to the nasopharyngeal vault and lie anterior to the usual site of origin of retention and pharyngeal bursa cyst. These are lined by stratified squamous epithelium, in keeping with their ectodermal origin.

Thymic Cysts

They are rare clinical entities, which arise in persistent thymic tissue, which may occur in any location between the angle of the mandible and midline of the upper neck to the sternal notch.

Histologically, the cyst is lined by squamous and cuboidal epithelium and thymic tissues are present in the wall.

Cysts of Salivary Glands

It is described in Chapter 26: Salivary Gland Disorders.

Parasitic Cyst/Hydatid Cyst

It is also called as 'hydatid disease' or 'echinococcosis'. It is caused by the larvae *E. granulosus*, the dog tapeworm and *E. multilocularis*.

Pathogenesis

- *Ingestion of tapeworm ova*—this tapeworm lives in the intestinal tract of the dog. Its ova are excreted in the faeces of the dog and may be ingested by the intermediate host like cattle sheep and pigs. Man is also susceptible as an intermediate host as dogs are common household pets, so may accidentally ingest the ova.
- *Hatching of ova*—the ingested ova hatch in the upper gastrointestinal tract, from where the small embryo permeate the intestinal mucosa and are distributed through the blood vessels and lymphatics to all parts of the body.

Clinical Features

- *Site*—it is more common in liver, but others are found in lung, bones and brain.
- *Symptoms*—usually they are asymptomatic but they enlarge progressively to cause pressure symptoms.
- *Signs*—liver involvement causes hepatomegaly and jaundice. Pulmonary hydatid cyst may cause shortness of breath and hemoptysis.
- *Complications*—rare complication of hydatid cyst includes rupture, suppuration and calcification of the cyst.

Oral Manifestation

- **Site**—intraorally, it is found in tongue and angle of mandible.
- **Appearance**—oral hydatid cyst presents as painless, progressively increasing, soft, elastic, and well circumscribed fluctuant swelling.
- **Symptoms**—there may be speech and mastication difficulties.

Radiographic Features

- There are four stages in the radiographic evolution of the disease. They are as follows:
 - **First stage**—there is cystic bone destruction involving medullary portion of the bone. The cysts are rounded and are described as 'grape like'. The medulla is expanded and disease is sharply demarcated.
 - **Second stage**—it is of secondary infection. In this stage, osteitis is the main change and new bone is formed beneath the periosteum. Septa between the cysts become coarser and the margins become less distinct. Pathologic fracture may occur.
 - **Third stage**—the third stage is characterized by confluent abscesses which break into the soft tissue.
 - **Fourth stage**—in fourth and final stage, bone is destroyed. The whole affected portion of the bone is represented by a 'meaningless jumble of calcareous bubbles'. The patient is likely to be crippled and bedridden.

Diagnosis

- **Clinical diagnosis**—painless, elastic and well circumscribed swelling in tongue may give clue to diagnosis.
- **Radiological features**—appearance of meaningless jumble of calcareous bubbles. In initial stage, it appears like grapes.
- **Laboratory diagnosis**—the outer layer is derived from fibrous tissue and is infiltrated by chronic inflammatory cells, eosinophils, lymphocytes and giant cells. The intermediate layer is white, non-nucleated and consists numerous delicate laminations. Innermost layer is a nucleated germinal layer. The cystic fluid is usually clear, albumin free and contains so called 'hydatid sand' consisting of brood capsule and scolices.

Management

- **Surgical**—the ideal treatment for hydatid cyst is surgical.
- **Prevention**—limiting contact between dogs and humans and deworming dogs at regular intervals are useful steps towards prevention.

Cysticercosis Cellulosae

Man develops cysticercosis through the larval form, cysticercus cellulosae, of the pork tapeworm *Taenia solium*. He can act as both the intermediate and the definitive host.

Pathogenesis

- **Ingestion of worm**—the adult worm may be ingested from inadequately heated or frozen pork. Alternatively, man may ingest the cysticerci themselves from infested pork and these develop into adult worms.
- **Attachment to wall of intestine**—these lives attach to the wall of the small intestine where they fully grow and at times, reach a length of 7 mm. Gravid proglottids or eggs begin to drop off and are passed in the faeces.
- **Penetration into intestinal mucosa**—in this way, man through contaminated food or from their own dirty hands may ingest them or they may be regurgitated into the stomach. In the stomach, their covering is digested off and the larval forms are hatched. It penetrate the intestinal mucosa and are then distributed through the blood vessels and lymphatics to all the parts of the body where they develop into cysticerci.

Clinical Features

- **Signs and symptoms**—it depends upon the site and the number of the cysticerci in the body. During the stage of invasion, there are no symptoms or slight muscular pain and mild fever may be present. CNS involvement produces serious effects.

Oral Manifestations

- **Site**—there is very little report about cysticercosis of oral region. In oral cavity, most common site involved is the tongue. Other sites involved are cheek and lips.
- **Signs**—there is a firm mass and contains watery fluid and coiled white structure apparently attached to the inner aspect of cyst.
- **Symptoms**—it is a painless, well circumscribed, elastic and fluctuant swelling.

Radiological Features

- **Appearance**—when the larvae die in the soft tissue, calcification takes place and it appears on the radiograph. The shadow of calcific density is rod shaped or resembles a "drop". Some of these appear more of less rounded when the projection of the rays happen to strike the larvae in its long axis.
- **Size**—the size of the shadow is 1 mm or more in width and 1.5 cm in length.

Diagnosis

- *Clinical diagnosis*—not specific as it is very rare in oral cavity.
- *Radiological diagnosis*—calcification is seen as 'drop' like
- *Laboratory diagnosis*—it shows dense fibrous outer capsule which is derived from host tissue. It contains a fairly dense inflammatory cell infiltrate consisting predominantly of lymphocytes, plasma cells and histiocytes. Few foci of dystrophic calcification are present in this capsule and some of these are concentrically laminated. The cyst lies within this membrane and contains larval form of *T. solium*.

Management

- *Surgical*—cutaneous cyst should be surgically removed.
- *Mebendazole*—Mebendazole has some value in the treatment.
- *Prevention*—pork should be properly cooked as preventive measures.

Syndromes Associated with Odontogenic Cysts

Jaw Cyst-Basal Cell Nevus-Bifid Rib Syndrome

It is also called as 'nevoid basal cell carcinoma', 'Gorlin's and Goltz's syndrome'. It is transmitted as autosomal dominant trait with poor degree of penetration and variable expressivity. It is caused by mutation in patched (PTCH), tumor suppressor gene.

Clinical Features

- *Age*—it appears early in life after 5 years and before 30 years.
- *Basal cell carcinoma*—Nevoid basal cell carcinoma is brownish colored papules predominant on skin, neck and trunk. Basal cell carcinoma is less aggressive in this syndrome than in solitary basal cell carcinoma.
- *Cutaneous abnormalities*—dermal cyst and tumors, palmar pitting, palmar and plantar keratosis and dermal calcinosis. Skin lesions are small, flattened, flesh colored or brownish papules occurring anywhere in the body, but are prominent on the face and trunk.
- *Skeletal abnormalities*—rib anomalies and brachymetacarpalism, bifid rib, agenesis, deformity and synostosis of rib; kyphoscoliosis, vertebral fusion, polydactyly and shortening of metacarpals.
- *Skull features*—there is frontal and temporoparietal bossing, resulting in an increased cranial circumference.
- *Ophthalmologic abnormalities*—hypertelorism with wide nasal bridge, dystopia canthorum, congenital blindness and internal strabismus.

- *Neurological anomalies*—mental retardation, calcification of falx cerebri and other parts of dura, agenesis of corpus callosum, congenital hydrocephalus and occurrence of medulloblastomas.
- *Sexual abnormalities*—Hypogonadism in males and ovarian tumors.

Oral Manifestations

- *Odontogenic keratocyst*—jaw lesions appear as multiple odontogenic keratocysts usually appearing in multiple quadrants.
- *Mandibular prognathism*—mild mandibular prognathism is also present in this syndrome.

Radiographic Features

- *Odontogenic keratocyst*—jaw cysts appear as a multiple cysts like radiolucency of variable size varying from few millimeters to several centimeters (**Fig. 13-47**). They occur most frequently in premolar-molar region.
- *Calcified falx cerebri*—radiopaque lines of calcified falx cerebri are prominent on PA projection.

Fig. 13-47: Multiple OKC seen in Gorlin's syndrome (Courtesy Dr Ashok L).

Differential Diagnosis

- *Multiple myeloma*—'Bence Jones' protein in the urine.
- *Metastatic carcinoma*—history of primary tumor.
- *Histiocytosis X*—does not have characteristic borders as seen in cyst.
- *Cherubism*—jaw expansion is common in it.

Management

- *Enucleation*—complete enucleation of the lesion should be done. Periodic examination should be done to check for recurrence.

Treatment of Cysts

Regression of Cysts without Surgical Treatment

There is good evidence that some small radicular cyst will regress if the necrotic pulp remnant and bacteria are

removed from the root canal of the causative tooth and the canal is effectively filled.

Circumscribed rounded zone of periapical bone destruction perhaps up to 1.5 cm in diameter will be seen in some patients to reduce in size and resolve over a period of month.

Marsupialization of Dental Cysts

It is known as '*Partsch's operation*' as it is discovered by Partsch. It involves making an opening into the cyst as large as practical and packing the cavity. It is a more effective way of emptying a cyst.

Indication

- *Age*—in a young child, with developing tooth germs.
- *Proximity to vital structure*—when proximity of the cyst to vital structure can create an oronasal or oroantral fistula or injure the neurovascular structure, this treatment modality should be considered.
- *Eruption of teeth*—in a young patient with a dentigerous cyst, marsupialization will permit the eruption of the unerupted tooth or any other developing tooth which has been displaced.
- *Vitality of teeth*—when the apices of many adjacent erupted teeth are involved within a large cyst, enucleation can prejudice the vitality of these teeth.
- *Fracture in cystic region*—it is the simplest way to treat a fracture complicating a large cyst of the mandible.

Advantages

- *Simple procedure*—this procedure at least for large cysts, is technically simple.
- *No general anesthesia required*—even quite large cysts can be dealt with under local anesthesia. As anesthesia of deeper recesses is not essential and this is particularly an advantage in the maxilla.
- *Preservation of adjacent mucosa*—because the deeper part of the lining is not disturbed, adjacent important structures are not put at the risk, i.e. the blood vessels to the apices of adjacent vital teeth, the inferior dental neurovascular bundle and the integrity of lining of the antrum or nose are well preserved.
- *Conservation of tooth*—marsupialization may be the best way to conserve the tooth of origin of a dentigerous cyst and to permit its eruption.
- *Prevention of fistula*—it prevents oronasal and oroantral fistula.
- *Reduce operating time and blood loss*—it reduces operating time and blood loss and helps in the shrinkage of cystic lining.
- *Preservation of alveolar ridge*—alveolar ridge is preserved.

Disadvantages

- *Regular postoperative care*—the need for regular postoperative care, possibly over a substantial period of time. It is necessary to supervise healing so that opening remains large in proportion to the underlying cavity. Prolonged follow-up visits and periodic irrigation.
- *Problems of opening*—a rapid reduction in the size of the opening may be difficult to prevent. Indeed an opening into a large cyst in the ramus may present significant problems.
- *Uneven reduction*—uneven reduction in size of the cavity may result in slit-like cavity, difficult to keep clean.
- *New cyst formation*—there is risk of invagination and new cyst formation.
- *Adjustment of plug*—regular adjustments of plug.

Enucleation

Enucleation allows for the cystic cavity to be covered by a mucoperiosteal flap and the space fills with blood clot which will eventually organized and form normal bone.

Indications

- *Odontogenic keratocyst*—it is indicated in treatment of odontogenic keratocyst.
- *Recurrent lesion*—recurrence of cystic lesion of any cyst type.

Advantages

- *Primary closure*—as the complete cyst is removed, primary closure of the wound is possible.
- *Rapid healing*—healing is rapid due to primary closure.
- *Less postoperative care*—postoperative care is reduced.
- *Thorough examination*—thorough examination of the entire cystic cavity can be done.

Disadvantages

- *Healing cannot be observed*—after primary closure, it is not possible directly to observe the healing of the cavity as with marsupialization.
- *Removal of unerupted teeth*—in young persons, the unerupted teeth in a dentigerous cyst will be removed with the lesion in this mode of treatment.
- *Mandibular weakening*—removal of large cysts will weaken the mandible making it prone to jaw fracture.
- *Damage of adjacent structure*—it will damage to adjacent vital structures.

Odontogenic Tumor of Jaw

Classification

First Classification

Benign

Epithelial

- With inductive changes in the connective tissue
 - Ameloblastofibroma
 - Dentinoma
 - Calcifying odontogenic tumor
 - Odontoameloblastoma
 - Odontoma
- Without inductive changes in the connective tissue
 - Ameloblastoma
 - CEOT
 - Epithelial atypia
 - Ameloblastic changes in odontogenic cyst

Mesenchymal

- Odontogenic myxoma
- Odontogenic fibroma
- Cementoma
- Periapical cemental dysplasia
- Cementifying fibroma
- Benign cementoblastoma

Malignant

Epithelial

- With inductive changes in the connective tissue
 - Ameloblastic fibrosarcoma
 - Ameloblastic odontosarcoma
- Without inductive changes in the connective tissue
 - Malignant ameloblastoma
 - Primary intraosseous carcinoma
 - Malignant changes in odontogenic cyst

Second Classification (By WHO)

Benign

Odontogenic epithelium without odontogenic ectomesenchyme

- Ameloblastoma
- Squamous odontogenic tumor
- Pindborg's tumor
- Clear cell odontogenic tumor

Odontogenic epithelium with odontogenic ectomesenchyme with or without dental hard tissue formation

- Ameloblastic fibroma
- Ameloblastic fibro-odontoma
- Ameloblastic fibro-dentinoma
- Odontoameloblastoma
- Adenomatoid odontogenic tumor
- Complex and compound odontoma

Odontogenic ectomesenchyme with or without including odontogenic epithelium

- Odontogenic fibroma
- Odontogenic myxoma
- Benign cementoblastoma

Malignant tumor

Odontogenic carcinoma

- Malignant ameloblastoma
- Primary intraosseous carcinoma
- Malignant variant of other odontogenic epithelial tumors
- Malignant changes in odontogenic cyst

Odontogenic sarcoma

- Ameloblastic fibrosarcoma
- Ameloblastic fibrodentinosa sarcoma

Third Classification (Benign Tumor)

Epithelial

- Ameloblastoma
- Adenoameloblastoma
- Enameloma
- Pindborg's tumor (CEOC)

Mesenchymal

- Dentinoma
- Cementoma
- Cementoblastoma
- Odontogenic fibroma

Mixed

- Ameloblastic fibroma
- Ameloblastic fibroodontoma
- Ameloblastic odontoma
- Odontogenic myxoma
- Compound composite odontoma
- Complex composite odontoma
- Odontogenic fibroma

Developmental

- Dense invaginatus or dilated odontome
- Dense evaginatus

Fourth Classification

Lesions consisting of odontogenic epithelium

- Ameloblastoma
- Adenomatoid odontogenic tumor
- Calcifying epithelial odontogenic tumor
- Calcifying odontogenic cyst

Lesions consisting of odontogenic epithelium and mesenchyme

- Ameloblastic fibroma
- Ameloblastic sarcoma

Lesions consisting of odontogenic epithelium and calcified dental tissues

- Odontoameloblastoma

Lesions consisting of calcified dental tissue, but without odontogenic epithelium

- Complex odontome
- Compound odontome
- Dens invaginatus (dilated odontome)
- Enameloma
- Dentinoma
- Cementoma

Lesions consisting of odontogenic mesenchyme

- Odontogenic fibroma
- Odontogenic myxoma

Benign Tumors

Ameloblastic Fibroma

It is also called as '*fibrous adamantinoma*', '*soft odontoma*', '*soft mixed odontoma*', and '*fibroadamantoblastoma*'. It is characterized by simultaneous proliferation of both epithelial and mesenchymal tissue without formation of enamel and dentin. If this tumor is left undisturbed, it will ultimately differentiate into a lesion known as '*ameloblastic fibroodontoma*'. It may mature into a complex odontoma. It is characterized by neoplastic proliferation of maturing and early functional ameloblasts as well as the primitive mesenchymal components of the dental papilla.

Origin

- *Dental follicle*—it develops from the dental follicle usually after the onset of calcification of the tooth.
- *Tooth bud*—in some instances, it may develop from tooth bud before onset of calcification and abort the formation of normal tooth.

Clinical Features

- *Age and sex distribution*—average age of occurrence is under 20 years with 40% of patients under the age of 10 years. There is slight predilection for occurrence in males.
- *Site*—it is developed in premolar, molar area of the mandible (**Fig. 14-1**).
- *Symptoms*—it is painless and expands slowly. There is bulging of the cortical plates rather than erosion through them. There is also migration of involved teeth.
- *Signs*—it enlarges by gradual expansion so that the periphery of bone often remains smooth. It is associated

Fig. 14-1: Swelling seen in premolar area in mandible in ameloblastic fibroma (Courtesy Dr Parate).

with unerupted teeth. It has got a slower clinical growth than ameloblastoma and does not tend to infiltrate between trabeculae of bone.

- **Size**—it reaches upto an approximate size of 1 to 8.5 cm.

Radiographic Features

- **Site**—it develops in premolar-molar area of the mandible. In some cases, it may involve the ramus and extend forward to the premolar-molar area.
- **Radiodensity**—it may present with cyst-like area of bone destruction or there may wide area of bone destruction (**Fig. 14-2**). As it is usually associated with an impacted tooth, it appears as pericoronal radiolucency.
- **Internal structure**—it may be either unilocular or multilocular and is associated with unerupted or missing tooth.
- **Margins**—are well defined often with sclerotic borders.
- **Effect on surrounding structure**—buccal and lingual expansion of jaw with intact cortical plates. Teeth may be inhibited from normal eruption or may be displaced in an apical direction.

Fig. 14-2: Cyst-like radiolucency seen in case of ameloblastic fibroma (Courtesy Dr Datarkar).

Diagnosis

- **Clinical diagnosis**—not so specific.
- **Radiological diagnosis**—not so specific. Sometimes, CT scan may be helpful to diagnose the tumor (**Fig. 14-3**).
- **Laboratory diagnosis**—biopsy shows scattered islands of epithelial cell in a rosette, long finger-like strands, nests and cords-like pattern. Cells resemble the primitive odontogenic epithelium. The mesenchymal component is made up of a primitive connective tissue.

Fig. 14-3: CT scan of ameloblastic fibroma (Courtesy Dr Bhaskar Patle).

Differential Diagnosis

- **Central giant cell granuloma**—it has a honeycomb pattern and is usually seen in anterior location.
- **Odontogenic myxoma**—finer trabeculation resembling a string of tennis racket pattern.
- **Central hemangioma**—honeycomb pattern and local gingival bleeding and pumping action of tooth or teeth.
- **Primordial cyst**—thick yellowish granular fluid.
- **Ameloblastoma**—associated with much older group.

Management

- **Curettage**—it can be done which has successful results in many cases. But there are chances of recurrence in this tumor.
- **Surgical excision**—aggressive surgical excision should be done for recurrent lesion.

Calcifying Epithelial Odontogenic Tumor

It is also called as '*Pindborg's tumor*' or '*calcifying ameloblastoma*'. It arises from the reduced enamel epithelium or dental epithelium. They are located within the bone and produce mineralized substance like amyloid. It forms 1% of all odontogenic tumors.

Clinical Features

- **Age and sex**—it is more common in men with an age range of 8 to 92 years with a mean age of 42 years.
- **Site**—mandible is more commonly affected than the maxilla in the ratio of 2:1 and developed in premolar-molar area (**Fig. 14-4**).

Fig. 14-4: Swelling seen in mandibular region due to calcifying epithelial odontogenic tumor (Courtesy Dr Bhaskar Patle).

- **Symptoms**—it is asymptomatic and only presenting symptom is a painless swelling. In rare cases, there is associated mild paresthesia.
- **Signs**—cortical expansion occurs. Palpation will show hard tumor with well defined or diffuse border. It is locally invasive with a high recurrence rate.
- **Peripheral calcifying epithelial odontogenic tumor**—there are only few reported cases of this type. It is presented as sessile gingival growth, seen on anterior gingiva (Fig. 14-5).

Fig. 14-5: Calcifying epithelial odontogenic tumor showing swelling in premolar area (Courtesy Abhishek Soni).

Radiographic Features

- **Radiodensity**—it may be totally radiolucent to mostly radiopaque area around the crown of unerupted teeth. The radiopacity is produced by mineralization of amorphous proteinaceous material generated by the tumor cells rather than the disorganized formation of dental tissue (Fig. 14-6).

- **Margin**—it may or may not be well demarcated from the surrounding normal tissue. It has got scalloped margin.
- **Internal structure**—there may be a combined pattern of radiolucency and radiopacities with many small, irregular bony trabeculae traversing the radiolucent area in many directions producing a multilocular or honey-comb pattern.

Fig. 14-6: Radiopaque calcified structure seen in CEOT (Courtesy Dr Tapasya Karamore).

- **Driven snow appearance**—later, it reveals a unilocular or a multilocular cystic lesion with numerous scattered radiopaque foci of varying sizes and density which gives it an appearance as that of 'driven snow' (Fig. 14-7).

Fig. 14-7: Typical driven snow appearance seen in CEOT (Courtesy Dr RN Mody).

- **Effect on surrounding structure**—it may displace the developing tooth or prevent its eruption. Expanded cortical plate can be visualized in buccal, lingual and vertical dimension.

Diagnosis

- **Clinical diagnosis**—not specific.
- **Radiological diagnosis**—typical driven snow appearance is seen.

- *Laboratory diagnosis*—biopsy shows polyhedral epithelial cells packed in large sheets. There is presence of calcification in large amounts and often in the form of 'Liesegang rings'.

Differential Diagnosis

- *Central odontogenic fibroma*—Histopathologically, fibroblasts are prominent and abundant.
- *Calcifying epithelial odontogenic cyst*—aspiration yield viscous granular yellow fluid.
- *Adenomatoid odontogenic tumor*—it is more common in anterior maxilla as compared to calcifying epithelial odontogenic tumor which is common in mandibular premolar-molar area.
- *Partially calcified odontoma*—it appears within the capsule.

Management

- *Conservative surgical excision*—it has limited invasive potential therefore local excision with limited margins is indicated. Simple enucleation can be done.

Odontoma

It is a hamartoma of odontogenic origin in which both epithelial and mesenchymal cells exhibit complete differentiation with enamel, dentin and cementum that are laid down in abnormal position. Odontome may arise from any of three dental tissues, i.e. enamel, dentin and cementum.

Origin

- There is growth of epithelial and mesenchymal component exhibiting complete differentiation with a result that functional ameloblasts and odontoblasts laid down in abnormal fashion.

Etiology

- *Genetic transmission*—it may occur due to mutant gene or interference with genetic control of tooth development.
- *Local trauma or infection*—in some cases of trauma or infection to tooth in developing stage may cause some alteration in ectomesenchymal interaction causing odontoma formation.

Classification

Ectodermal origin

- *Enameloma* (enamel pearl, enamel nodule).

Mesodermal origin

- *Dentinoma*
- *Cementoma*.

Mixed

- *Complex composite odontoma*—non-discrete masses of dental tissue.
- *Compound composite odontoma*—multiple well formed teeth.
- *Compound-complex odontoma*—some tumors contain not only multiple teeth like structures, but also calcified masses of dental tissue in a haphazard manner, such lesion are called as compound-complex odontoma.
- *Geminated odontoma*.
- *Dilated odontoma with dens in dente*.

Enameloma

It is also called as 'enamel nodule', 'enamel drop' or 'enamel pearl'. It is a small focal excessive mass of enamel on the surface of the tooth. It is formed by small group of misplaced ameloblasts. This enamel may contain a small core of dentin and rarely, small strands of pulp tissue extending from pulp chamber or root canal of the tooth.

Clinical Features

- *Site*—enamel pearls are most commonly found in the bifurcation or trifurcation of roots or on the surface near the cemento-enamel junction. The most common site is upper molar.
- *Appearance*—it appears as a tiny globule of enamel firmly adherent to the tooth.
- *Significance*—in some cases, it occupies such a position on cemento-enamel junction that leads to pocket formation which may predispose to periodontal diseases.

Radiographic Features

- *Radiodensity*—the little mass is made up of enamel which absorbs more X-rays than the adjacent dentin so that it appears as radiopaque shadow.
- *Shape*—it is usually hemispherical.
- *Size*—it varies in size from one millimeter to three or more.
- *Appearance*—it appears as rounded, well circumscribed density associated with root.
- *Dense projection*—it is best seen radiographically when it is situated on mesial and distal side of the tooth so that it appears in profile. It then appears as dense projection which is continuous with the tooth substance.

Diagnosis

- *Clinical diagnosis*—tiny enamel globule seen on enamel.
- *Radiological diagnosis*—radiopaque shadow on enamel.
- *Laboratory diagnosis*—it consists of enamel.

Differential Diagnosis

- *Projection shadow*—it happens when the angulation of the rays is such that they do not pass freely between the roots where they approximate at the bifurcation. The result is that portion of distal aspect of the mesial root is projected over the mesial portion of distal root. It will add radiographic density which results in more or less rounded shadow of greater density where the roots converge at the bifurcation. To differentiate it from enameloma, take radiograph in such a way that the rays should pass between the contiguous portions of the roots.

Management

- *Removal of mass*—mass has to be removed if it is causing periodontal diseases.

Dentinoma

It is a rare tumor of odontogenic origin composed of immature connective tissue, odontogenic epithelium and irregular or dysplastic dentin.

Clinical Features

- *Age and sex*—it is seen in patients younger than 36 years with an average age of 26 years with no sex predilection for occurrences.
- *Site*—it is predominately seen in the mandibular molar area and is frequently associated with an impacted tooth.
- *Symptoms*—patient notices a swelling over a variable period of time with pain.
- *Sign*—perforation of mucosa and subsequent infection may be present. There may be redness of overlying mucosa with discharge.

Radiographic Features

- *Radiodensity*—radiopaque mass associated with the crown of unerupted tooth.
- *Internal structure*—it contains either a large, solitary, opaque mass or numerous smaller, irregular radiopaque masses of calcified materials which may vary considerably in size.
- *Bone*—it may cause local destruction of bone.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—radiopaque mass with crown of tooth.
- *Laboratory diagnosis*—biopsy shows irregular dentin, which has been termed as dentinoid or osteodentin. There is also presence of undifferentiated odontogenic epithelium.

Management

- *Surgical*—surgical excision with thorough curettage of the area.

Complex and Compound Odontoma

It is a non-aggressive lesion that is more likely to be a hamartoma than a neoplastic growth.

Etiology

- *Trauma*—local trauma or infection may lead to production of such a lesion.
- *Genetic*—they are either inherited or are due to a mutant gene or interference, possibly postnatal, with genetic control of tooth development.

Mechanism

- *Differentiation of epithelial and mesenchymal cells*—both the epithelial and mesenchymal cells exhibit complete differentiation with the result that functional ameloblasts and odontoblasts form enamel and dentin.
- *Pattern*—it is laid down in an abnormal pattern because of failure of cells to reach the morphodifferentiation stage. Lesion is composed of more than one type of tissue, for this reason it is called as composite odontome.
- *Compound composite odontome*—in some composite odontomes, the enamel and dentin are laid down in such a fashion that the structure bears a considerable anatomical resemblance to that of normal teeth except they are often smaller than the typical teeth, which have been termed as compound composite odontome.
- *Complex composite odontome*—when calcified dental tissues are simply arranged in an irregular mass bearing no morphological similarity even to rudimentary tooth then that form is called as complex composite odontome.

Clinical Features

- *Age and sex*—it is more commonly seen in first and second decade of life. Most begin to form while normal dentition is developing. Slight predilection for occurrence in males.
- *Site*—compound odontome occurs in incisor, canine area of maxilla and complex odontome occurs in mandibular 1st and 2nd molar area. Unusual situation includes the maxillary sinus, inferior border of the mandible, ramus and condylar region.
- *Frequency*—compound odontome is twice as common as complex odontome.
- *Size*—compound odontoma is between 1 to 3 cm in diameter. It usually remains small and diameter of the mass only occasionally increases than that of the tooth.

- **Symptoms**—patient may notice alveolar swelling in the jaw. This swelling will cause facial asymmetry (**Fig. 14-8**). In some cases, signs of infection may be present.

Fig. 14-8: Odontoma causing swelling on right side of face causing facial asymmetry (Courtesy Dr Parate).

- **Signs**—it is common for a tooth or teeth to be absent from the arch in the presence of an odontome. On palpation expansion of the jaw (**Fig. 14-9**) may be noticed.

Fig. 14-9: Intraoral picture of same patient (**Fig. 14-8**) showing expansion of alveolar bone (Courtesy Dr Parate).

- **Teeth**—impaction malpositioning, diastema, aplasia, malformation and deviation of adjacent teeth are associated with 70% of odontoma.
- **Development of cyst**—sometime, cyst develops in relation with a complex odontome and compound odontome, but it is very rare.

Radiographic Features

General

- **Site**—it is situated between the roots of teeth.

- **Appearance**—it appears as an irregular mass of calcified material surrounded by narrow radiolucent bands with a small outer periphery.

Compound composite odontome

- **Appearance**—compound type shows number of teeth like structures in the region of the canine (**Fig. 14-10**).

Fig. 14-10: Compound odontoma showing shapeless tooth structure (Courtesy Dr Parate).

- **Internal structure**—there is cluster of small shapeless dense masses of solid tissue having equal or more density, depending on the size of the mass. There may be many masses each of which has own dark line surrounding it. In some cases, there may be presence of two or more teeth-like masses having conical enamel-capped crowns and with fusion of the radicular portion.
- **Characteristic of teeth**—if only few teeth are present, a periodontal and pericoronal characteristic of unerupted teeth may be discernible on each individual tooth. If a large number of teeth are present, the radiopaque mass is surrounded by a radiolucent line that represents the pericoronal space of the unerupted teeth.
- **Margin**—borders are well defined in both the cases but vary from smooth to irregular and may have hyperostotic borders.

Complex composite odontome

- **Appearance**—complex composite odontoma appears as a dense radiopaque object sometimes lying in clear space (**Fig. 14-11**). Density is greater than that of bone and to greater than or equal to the teeth.
- **Internal structure**—it shows a well defined radiolucency containing irregular masses of calcified tissue. It is associated with unerupted teeth (**Fig. 14-12**).

Cystic odontome

- **Cystic complex odontome**—it will reveal the solid mass of the odontome but without any associated unerupted

Fig. 14-11: Complex odontome showing well defined radiopacity (Courtesy Dr Parate).

Fig. 14-12: Complex odontome showing radiopacity but not resembling tooth structure.

tooth. There is dark shadow which represents the cystic cavity and it has well defined and corticated margins except when infection supervenes (**Fig. 14-13**).

- *Cystic compound odontome*—there is an area of bone destruction which appears as a dark shadow having well defined margins lined by a thin white layer of cortical border. Within the cystic cavity there are numerous white opacities which vary in size and shape. In some cases, there are small amorphous granular densities scattered throughout the cavity and in some cases there are small denticles with enamel caps or without any distinction of the component mass.

Differential Diagnosis

- *Difference between compound and complex type*—compound odontome has more than one fragment while in complex, it is one solid mass. Compound is seen most commonly

Fig. 14-13: Cystic complex odontome showing radiopacity surrounded by radiolucent capsule (Courtesy Dr Bhaskar Patle).

in maxillary canine and incisor region while complex is more commonly seen in mandibular molar area.

- *Cementifying or ossifying fibroma*—odontoma is associated with unerupted molar teeth and more radiopaque than fibroma and discovered at much younger age than fibroma.
- *Adenomatoid odontogenic tumor*—rarely as opaque as the complex type and found in association with maxillary canines.
- *Periapical cemental dysplasia*—smaller than complex type and is limited to mandibular anterior region.
- *Calcifying epithelial odontogenic tumor*—rare, less opaque and develops in the midline.
- *Fibrous dysplasia*—mottled or smoky pattern poorly defined borders.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—compound shows shapeless mass of tooth structure while complex show disorganized mass of tooth structure.
- *Laboratory diagnosis*—biopsy shows multiple tooth structures contain in loose fibrous matrix (compound) and mature tubular dentin (complex).

Management

- *Local excision*—simple local surgical excision is the treatment of choice.

Gemination and Geminated Composite Odontome

These two terms appear to be used interchangeably with each other. The attempt at division of a single tooth germ by an invagination, with resultant incomplete formation of two teeth is gemination (**Fig. 14-14**), while the addition of

more or less misshapen one or both components may be termed as geminated composite odontome. Geminatio is discussed in detail in Chapter 9: Teeth Anomalies.

Fig. 14-14: Invaginated odontome (Courtesy Dr Mody).

Ameloblastoma

First detailed description of ameloblastoma was given by 'Falkson' in 1879. It is an aggressive tumor that appears to be arising from remnants of dental lamina or dental organs. It represents 1% of all oral tumors and 11% of odontogenic tumors. It is the most common epithelial tumor producing minimal inductive changes.

There are different names given to this tumor. Term 'adamantine epithelioma' was given by Malassez in 1885. It was replaced by ameloblastoma in 1934 by Churchill. It is also called as 'adamantinoma', 'adamantinoblastoma', 'epithelial odontome' and 'multilocular cyst'.

Definition

It is a benign but locally invasive polymorphic neoplasm consisting of proliferating odontogenic epithelium which is usually in a follicular or plexiform pattern, lying in fibrous stroma.

Etiology

- **Irritation**—it might be considered as one of the etiological factors as it often occurs in the posterior region of the mandible which is most susceptible to irritation.
- **Infection**—Robinson found that 1/3rd of the cases have history of oral infection, extraction of teeth and injuries to teeth.

- **Trauma**—trauma can be a causative factor for ameloblastoma.
- **Dietary deficiency**—dietary deficiency has been considered to be a possible factor, e.g. pronounced defect in development of tooth germ as seen in rickets may lead to irregularity in the ameloblastic layer.
- **Virus**—injection of polyoma viruses and nitrosoureas have been shown to produce ameloblastoma-like lesion in animals.

Classification

- **On pathological basis**
 - Conventional ameloblastoma
 - Unicystic ameloblastoma
 - Peripheral ameloblastoma
 - Pituitary ameloblastoma
 - Adamantinoma of long bones
- **On histological type**
 - Follicular ameloblastoma
 - Plexiform ameloblastoma
 - Acanthomatous ameloblastoma
 - Basal cell ameloblastoma
 - Unicystic ameloblastoma
 - Plexiform unicystic ameloblastoma
 - Granular cell ameloblastoma
 - Papilliferous ameloblastoma
 - Hemangioameloblastoma
 - Desmoplastic ameloblastoma
 - Clear cell ameloblastoma
 - Dentinoameloblastoma
 - Melanoameloblastoma
 - Keratoameloblastoma.

Pathogenesis

The resemblance of the tumor epithelium to the normal enamel organ indicates that ameloblastoma arises from dental epithelium. The possibilities for its development are as follows.

- **Enamel organ**—due to histological similarities such as its origin, it has been thought that the tumor growth starts at an early age; i.e. during the period of existence of enamel organ but most of the patients are middle aged i.e. in a period which is long after regression of the enamel organ. However, the occasional occurrence of the tumor as a unilocular cystic lesion surrounding the crown of an unerupted tooth also suggests that in some cases, the enamel organ may give rise to it.
- **Cell rests**—cell rests of enamel organ either remnants of dental lamina or remnants of Hertwig's sheath i.e. epithelial cell rests of Malassez have the potential of transforming into ameloblastoma.

- *Epithelium of odontogenic cysts, i.e. from dentigerous cyst and odontoma*—this may be possible as the epithelium in the wall of the cyst and that of ameloblastoma are derived from the same embryonic source.
- *Oral mucosa*—basal cells layer of the oral epithelium of jaws can be the origin. The reason behind this is that there is communication between the tumors and overlying mucosal epithelium as seen in peripheral ameloblastoma.
- *Heterotrophic epithelium*—heterotrophic epithelium in other parts of the body especially of pituitary gland can serve as source of origin.

Clinical Features

- *Incidence*—ameloblastoma accounts for approximately 1% of all oral tumors and 11% of all odontogenic tumors.
- *Sex and race*—it has slight predilection for males and often seen in blacks.
- *Age*—most patients are between 20 to 50 years of age with mean age of discovery being 40 years. The tumor can occur in young children. Unicystic type of ameloblastoma is more common in the 2nd and 3rd decade and the extrasosseous form is more common in the older age group.
- *Site*—it develops in the molar ramus area (approximately $\frac{3}{4}$ th of cases) in the mandible and also occurs in maxilla in third molar area, followed by the maxillary sinus and floor of the nose. The right side of the mandible is affected slightly more as compared to the left side.
- *Preceding factors*—neoplasm is frequently preceded by extraction of teeth, cystectomy and some other traumatic episodes.
- *Onset*—it begins as a central lesion of the bone which is slowly destructive but tends to expand bone rather than perforating it.
- *Symptoms*—patient notices a gradually increasing facial asymmetry (**Fig. 14-15**). Teeth in involved region are displaced and become mobile (**Fig. 14-17**). Pain and paresthesia may occur, if the lesion is pressing upon a nerve or is secondarily infected.
- *Signs*—in later stages, the lesion may show ovoid and fusiform enlargement that is hard but non-tender. If it is left untreated for many years the expansion may be extremely disfiguring (**Fig. 14-16**), fungating and ulcerative type of growth characteristic of carcinoma can be seen.
- *Eggshell cracking*—as tumor enlarges, palpation may elicit a hard sensation or crepitus. Surrounding bone may become thin so that fluctuation and 'eggshell cracking' may be elicited.
- *Maxillary ameloblastoma*—maxillary lesions are more dangerous than mandibular lesions due to tendency for

Fig. 14-15: Facial asymmetry in patient of ameloblastoma.

Fig. 14-16: Disfigurement of face due to huge swelling of ameloblastoma (Courtesy Dr Bhaskar Patle).

Fig. 14-17: Intraoral view of ameloblastoma showing displacement of tooth.

the former lesion to spread more extensively in the more porous maxillary bone and possibility of the involvement of the cranial base. It may extend into the paranasal air sinuses, orbit or the nasopharynx.

- **Mural ameloblastoma**—ameloblastoma may form from the epithelial lining of dentigerous cyst and in such cases, it is called as '*mural ameloblastoma*'.
- **Spread**—this tumor causes expansion of the bone rather than destruction. Ameloblastoma infiltrates cancellous bone but it is largely confined by the compact bone. It never infiltrates haversian canal. It infiltrates between the trabeculae of the cancellous bone and hence leaves them intact for some duration. Hence, the actual margins of the lesion are much greater than radiological margin which accounts for recurrence rate, if neglected. As the cortical plates of maxilla are thin, it does not possess an effective barrier to the spread of ameloblastoma into adjacent vital structures.

Radiographic Features

- **Radiodensity**—in early stages, there is area of bone destruction which is well defined and is indicative of slow growth with hyperostotic borders.
- **Margins**—outline is smooth, scalloped, well defined and well corticated. The walls of the cavity are coarse. In some cases the margins of the tumor are lobulated.
- **Internal structure**—usually it is multilocular but may be unilocular (**Fig. 14-18**). Coarse or fine trabeculae may be present within the tumor and it is common for the free margins of the tumor to be devoid of bony covering.

Fig. 14-18: Unilocular ameloblastoma seen in posterior region of mandible.

- **Appearance**—there is presence of septa in the lesion. In some cases, number and arrangement of septa may give

the area a '*honeycomb appearance*' (**Fig. 14-20**) (numerous small compartments) or a '*soap bubble appearance*' (larger compartments) (**Fig. 14-19**). In advanced stages, perforated cortical plate may contribute to a multilocular appearance.

Fig. 14-19: Soap bubble appearance seen in ameloblastoma.

Fig. 14-20: Honeycomb appearance seen in ameloblastoma.

- **Progress**—in early stage ameloblastoma presents as bubble like appearance with fairly large, round and distinct compartments. As the tumor grows and expands, the compartments may coalesce and fuse. As the lesion again increases in size, the cortex is expanded and destroyed.
- **Subclinical lesion**—a small subclinical lesion usually presents in radiographs as many small rounded cavities in the bone having sharply defined and sometimes corticated borders. In some cases, there are two rounded and well defined small cavities having good bony cortex; in the center of which there is a small white dot.
- **Unicystic variety**—in case of mural ameloblastoma, the radiological appearance is like unicystic variety (**Fig. 14-21**).

Fig. 14-21: Unilocystic ameloblastoma (Courtesy Dr Mody).

Fig. 14-22: Ameloblastoma also showing soft tissue swelling in the radiograph (Courtesy Dr Bhaskar Patle).

Figs 14-23A and B: CT scan of ameloblastoma (Courtesy Dr Iswar).

- *Effect on surrounding structures*—the jaws are likely to be enlarged, depending on the overall size of the tumor. Extensive root resorption may occur. Thickening of membrane, cloudiness and destruction of walls are the finding when the sinus is involved.
- *Eggshell of bone*—expansion and thinning of cortical plate occurs leaving thin 'eggshell of bone'. Perforation of bone is a late feature.
- *CT features*—computed tomography can explain exact nature and dimension of the lesion.
- *Radiological diagnosis*—honeycomb appearance, soap bubble appearance seen in posterior mandible with bony expansion.
- *Laboratory diagnosis*—in biopsy various types of ameloblastoma can be seen. It can be follicular (small discrete islands of tumor cells with peripheral layer of cuboidal and columnar ameloblast-like cells), plexiform type (ameloblasts-like tumor cells arranged in irregular masses or more frequently, as network of interconnecting strands of cells, each of which is bounded by layer of columnar cell and between these layers found stellate reticulum-like cells), Acanthomatous type (cells occupying the position of stellate reticulum undergo squamous metaplasia, with keratin formation in the central portion of tumor islands), granular (stellate reticulum cells takes coarse granular eosinophilic appearance), basal type (show baseloid pattern), unicystic (same like dentigerous cyst with ameloblastic changes).

Diagnosis

- *Clinical diagnosis*—swelling in posterior mandible with expansion and eggshell cracking will give clue to diagnosis.

Types of Ameloblastoma

Peripheral Ameloblastoma

It is also called as 'extraosseous ameloblastoma'. It is a tumor which occurs in the soft tissue outside and overlying the alveolar bone. It originates from either the surface epithelium or the remnants of dental lamina.

Clinical Features

- **Age and sex distribution**—it is common in males and more commonly found in middle age group.
- **Site**—it is seen on the mandibular gingiva in the molar-premolar region. Some cases also seen in buccal mucosa and maxillary tuberosity area.
- **Symptoms**—the patient complains of an intraoral mass which is growing in size and interfering with speech, mastication and esthetics.
- **Sign**—mass is mildly tender on palpation when ulcerated and bleeding may occur on slight touch.
- **Appearance**—The lesion appears nodular swelling on gingiva varying in size from 3 mm to 2 cm in diameter.

Radiological Features

- **Bone erosion**—sometimes underlying bone may exhibit evidence of pressure resorption in the form of saucer-shaped depression beneath the tumor.

Diagnosis

- **Clinical diagnosis**—not so specific.
- **Radiological diagnosis**—saucer shaped bone depression beneath the tumor mass may suspect the lesion.
- **Laboratory diagnosis**—biopsy shows same pattern as seen in intraosseous ameloblastoma.

Management

- **Surgery**—simple surgical excision of the lesion is treatment of choice. Prognosis of this tumor is very good.

Pituitary Ameloblastoma

It is also called as 'craniopharyngioma' or 'Rathke's pouch tumor'.

- **Origin**—it occurs in anterior lobe, which is of ectodermal origin. The lobe is derived from Rathke's pouch, an outgrowth of oral ectoderm. The pouch gives rise to craniopharyngeal duct, which in due course degenerates itself leaving residues of squamous epithelial cells. From these squamous epithelial cells, ameloblastoma-like tumor develops.
- **Age**—it is most common in childhood and adolescents before the age of 25 years.

- **Location**—it may be located within the sella tursica or commonly in suprasellar space. It grows as a pseudo-encapsulated mass causing pressure effect and often destroys the pituitary gland.
- **Symptoms**—they are related to destruction of pituitary gland (diabetes insipidus) or to compression of nearby cranial nerve.

Adamantinoma of Long Bones

- **Origin**—it is derived from epithelial rests misplaced during the course of development. Trauma causing implantation of epithelium with subsequent tumor formation.
- **Site**—it occurs in tibia, ulna, femur and occasionally in others bone.
- **Clinical course**—some lesions behave aggressively and sometimes are metastasizing.

Differential Diagnosis (Radiological)

Small and unilocular ameloblastoma

- **Residual cyst**—there is history of extraction of the teeth.
- **Lateral periodontal cyst**—found in incisor, canine and premolar area in maxilla and ameloblastoma occur in mandibular molar area.
- **Giant cell granuloma**—anterior to the molar and ameloblastoma occur in molar area.
- **Traumatic bone cyst**—occurs in mid-twenties and ameloblastoma common in 3rd and 4th decade.
- **Primordial cyst**—same as traumatic bone cyst.

Multilocular ameloblastoma

- **Odontogenic myxoma**—history of missing tooth and has a presence of septa that divide the image into much finer course than those in ameloblastoma.

Management

- **Curettage**—it is least efficient as it makes recurrence inevitable. Curettage may leave bone that is invaded by tumor cells.
- **Intraoral block excision**—excision of a block of bone may be recommended if the ameloblastoma is small. The segment in which the tumor is contained is removed with a safe margin of normal bone.
- **Extraoral En-block resection**—if the lesion is large and horizontal ramus is involved then this is carried out.
- **Peripheral osteotomy**—it is a procedure which allows complete excision of the tumor but at the same time a part of bone is retained which preserves the continuity of the jaw. The procedure is based on the observation that cortical inferior border of the horizontal body, the posterior border of the ascending ramus and condyle are generally not involved by tumor process. These areas are resistant and strong because of the dense cortical bone. Bone regeneration will proceed from such areas with considerable restoration of the jaw architecture.

Squamous Odontogenic Tumor

It is well differentiated odontogenic tumor composed of islands or sheets of squamous epithelium that lack recognizable features of enamel organ differentiation. It arises from the cell rests of Malassez, although hamartomatous epithelial transformation is also found.

Clinical Features

- *Age and sex*—there is a wide age distribution in the range of 11 to 67 years with mean age 40 years and females are more commonly affected than the males.
- *Site*—it occurs with equal frequency in maxilla and mandible. In maxilla, it occurs in incisor-cuspid area and in the mandible; it has got a predilection for the bicuspid-molar area.
- *Onset*—it is slowly growing tumor.
- *Symptoms*—it is usually asymptomatic but there may be mobility of the involved teeth, pain, tenderness to percussion and occasionally abnormal sensation.

Radiological Features

- *Site*—it occurs usually in association with the cervical portion of the tooth.
- *Radiodensity*—it is well circumscribed radiolucent area.
- *Shape*—it presents as a semicircular or roughly triangular area (**Fig. 14-24**).
- *Margin*—border may or may not be sclerotic.

Fig. 14-24: Semicircular shape radiolucency seen squamous odontogenic tumor.

Diagnosis

- *Clinical diagnosis*—not so specific.

- *Radiological diagnosis*—semicircular radiolucency present between the roots.
- *Laboratory diagnosis*—biopsy shows islands of squamous epithelium without peripheral palisaded or polarized columnar cells.

Differential Diagnosis

It is a rare lesion so, it should not be high on the differential diagnostic list when considering radiolucent jaw lesions. If at exploration one discovers a solid fleshy lesion which is associated with a vital tooth root on cervical portion then squamous odontogenic tumor is the most likely diagnosis.

Management

- *Surgery*—conservative enucleation and curettage is usually curative with a low recurrence rate.

Odontogenic Myxoma

It is also called as 'odontogenic fibromyxoma', 'myxofibroma'. It is a rare non-invasive neoplasm that arises from the dental papilla, follicular mesenchyme and periodontal ligament.

Origin

- *Overgrowth of dental papilla*—the myxomatous tissue arises as a direct outgrowth of dental papilla of tooth or as an indirect effect of odontogenic epithelium on mesenchymal tissue.
- *Changes in fibrous tissue*—as a direct myxomatous change in fibrous tissue.

Clinical Features

- *Age and sex*—it is slightly more common in females with an age range of 10 to 30 years.
- *Incidence*—it accounts for 3 to 6% of odontogenic tumors.
- *Site*—mandible is more commonly affected than maxilla by a ratio of 3:1. Premolar-molar area in mandible and zygoma in maxilla. Rarely tumor may appear in the condylar region.
- *Symptoms*—they are associated with congenitally missing teeth. The growth rate is slow and pain is variable. There is a hard swelling which may be sometime large enough to produce facial asymmetry.
- *Signs*—sometimes it perforates the cortical plate producing a bosselated surface (several small nodules on the surface).
- *Appearance*—it may appear as fusiform swelling that may be hard and or may be covered by a layer of bone of only eggshell.

- **Teeth**—it may cause expansion and become huge if unattended. Teeth will be displaced and loosened but root resorption is rare.
- **Maxillary sinus**—it can invade maxillary sinus and cause exophthalmos.

Radiographic Features

- **Internal structure**—it may be either unilocular or multilocular. It may be mixed radiopaque-radiolucent lesion. Compartments tend to be angular. They may be separated by straight septa that form square, rectangular or triangular spaces. The central portion is transversed by fine gracile trabeculation.
- **Margins**—it is usually well defined but sometimes it may be poorly defined. It may be scalloped between the roots of adjacent teeth.
- **Tennis racket or honeycomb appearance**—locules are small and uniform with typical honeycomb appearance or strings of tennis racket (**Fig. 14-25**). Trabecular are arranged in right angle to each other.
- **Soap bubble appearance**—exceptionally, fine septa crosses the radiolucent area producing a soap bubble appearance.
- **Roots**—roots rarely show resorption.
- **Margin**—some of the myxomas resemble a dental cyst and instead of the smooth borders seen with the cyst, there are crenated margins.

Fig. 14-25: Tennis racket pattern seen in odontogenic myxoma.

Diagnosis

- **Clinical diagnosis**—missing teeth with hard swelling may suspect this disease.
- **Radiological diagnosis**—tennis racket pattern seen in odontogenic myxoma.
- **Laboratory diagnosis**—biopsy shows loosely arranged, spindle shaped and stellate cells, many of which have long fibrillar processes that tend to be intermeshed.

Differential Diagnosis

- **Central giant cell granuloma**—anterior location in mandible.
- **Ameloblastoma**—usually occurs in older patients.
- **Cherubism**—younger age group and bilateral involvement.
- **Giant cell lesions of hyperthyroidism**—history of kidney disease and abnormal serum chemistry.
- **Metastatic carcinoma**—older age group and presence of primary tumor.
- **Aneurysmal bone cyst**—it is tender and painful.
- **Central hemangioma**—it is not associated with missing tooth. Pumping tooth syndrome is seen in hemangioma with aspiration being useful.

Management

- **Surgical excision**—tumors may be difficult to enucleate due to their loose consistency, therefore surgical excision is indicated.
- **Resection**—resection with generous amount of surrounding bone.

Peripheral Odontogenic Fibroma

It is also called as 'peripheral ossifying fibroma', 'peripheral ameloblastic fibrodentinitoma', 'calcifying fibrous epulis' 'peripheral fibroma with calcification'. It consists of fibrous tissue containing nests of odontogenic epithelium and calcified material that resembles cementum.

It involves periodontal ligament superficially and contains odontogenic epithelial nests and deposits of cementum, bone and dystrophic calcifications scattered throughout the background of fibrous tissue.

Etiology

- **Irritation**—it is associated with irritation (overextended margin of faulty restoration and deposits of calculus).

Clinical Features

- **Sex and age distribution**—age 5 to 25 with peak at 13 years. Females are affected more than males.
- **Common sites**—it occurs more commonly in the mandible. It occurs exclusively on free margin of the gingiva and involves interdental papillae.
- **Symptoms**—it is usually asymptomatic. It is slow growing, often present for a number of years. Some lesions grow large enough to cause facial asymmetry.
- **Signs**—they are solid and firmly attached to the gingival mass, sometimes arise between teeth and sometimes displaces the teeth (**Fig. 14-26**).

- **Appearance**—it is well demarcated mass of tissue on the gingiva with a sessile or pedunculated base. Early lesions are soft, quite vascular and red and bleed readily. More mature lesions are firm, fibrous and pale pink.

Fig. 14-26: Peripheral odontogenic fibroma presenting as mass attached to gingiva (Courtesy Dr Abhishek Soni).

Radiographic Features

- **Bone erosion**—on rare occasion, there may be superficial erosion of bone.
- **Calcification**—there may be presence of some radiopaque foci within the tumor mass which occur due to calcifications within the tumor.

Diagnosis

- **Clinical diagnosis**—sessile mass attached to gingiva may suspect peripheral odontogenic fibroma.
- **Radiological diagnosis**—not specific.
- **Laboratory diagnosis**—biopsy shows cellular fibrous connective tissue parenchyma with non-neoplastic islands, strands and cords of columnar or cuboidal cells.

Differential Diagnosis

- **Chondrosarcoma and osteogenic sarcoma**—less frequent gingival lesion, severe bony changes, asymptomatic with widening of PDL.
- **Inflammatory hyperplasia**—no separation of teeth occurs.

Management

- **Surgical excision**—simple surgical excision and submitted for microscopic examination for confirmation of diagnosis.

Central Odontogenic Fibroma

It is a lesion around the crown of an unerupted tooth resembling a small dentigerous cyst. But some say that

it is a hyperplastic dental follicle and not an odontogenic tumor. It may occur centrally or in the periphery.

Clinical Features

- **Age and sex distribution**—it occurs more frequently in older individual with mean age of 40 years. There is marked female predilection.
- **Site**—it is more common in maxilla and in anterior region.
- **Symptoms**—it is generally asymptomatic except for the swelling of the jaws.
- **Signs**—it may cause localized bony expansion and loosening of teeth.

Radiological Features

- **Radiodensity**—it produces an expansile radiolucency similar to that of ameloblastoma.
- **Site**—it is often associated with apices of erupted teeth.
- **Margin**—margins are well defined and sclerotic.
- **Internal structure**—it can be unilocular but larger lesions tend to be multilocular.
- **Effect on surrounding structures**—larger lesions may cause root divergence and resorption.

Diagnosis

- **Clinical diagnosis**—not so specific.
- **Radiological diagnosis**—multilocular radiolucency in anterior maxilla may suspect central odontogenic fibroma (**Fig. 14-27**).
- **Laboratory diagnosis**—biopsy shows tumor mass made up of mature collagen fibers interspersed usually by many plumps of fibroblasts that are very uniform in their placement and tend to be equidistant from each other.

Fig. 14-27: Multilocular appearance of central odontogenic fibroma present in anterior maxilla.

Management

- *Curettage and enucleation*—central odontogenic fibroma is treated with enucleation and curettage. It does not recur.

Granular Cell Odontogenic Tumor

It is also called as '*granular cell odontogenic fibroma*'. It is more cellular. It consists of large eosinophilic granular cells with cords and islands of odontogenic epithelium.

Clinical Features

- *Age and sex distribution*—it occurs more frequently in older person (more than 40 years of age). There is slightly female predilection.
- *Site*—it is common in premolar and molar area of mandible.
- *Symptoms and sign*—lesion is painless with expansion of the jaw is noted.

Radiological Features

- *Appearance*—it appears as well demarcated radiolucency. It is unilocular or multilocular.
- *Calcification*—small degree of calcification is noted in the lesion.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—calcification in unilocular radiolucency may suspect the lesion.
- *Laboratory diagnosis*—biopsy shows large eosinophilic granular cells. Narrow cords or small islands of odontogenic epithelium are scattered in granular cells area. Small cementum-like calcification is also seen.

Management

- *Curettage*—simple curettage of the lesion should be carried out. No recurrence is reported.

Periapical Cemental Dysplasia

It is also called as '*fibrocementoma*', '*sclerosing cementum*', '*periapical osteofibrosis*', '*periapical fibrosarcoma*'. It is a reactive fibro-osseous lesion derived from the odontogenic cells in the periodontal ligament. It is located at the apex of the teeth. It is usually discovered as an incidental finding during routine radiographic surveys.

Etiology

- *Local factors*—it occurs as a result of trauma, chronic irritation.

- *Hormone*—there is possibility that female sex hormones may be an etiologic factor since the disease is commonly found in women.
- *Others*—nutritional deficiency, metabolic disturbances, past history of syphilis, endocrinal imbalance and anomalous development.

Pathogenesis

Bone at the apex of the affected tooth may be replaced by fibrous tissue which may be small in amount or occupy an area of a square inch or more →the fibrous tissue may remain unchanged for months to years but in most instances, there is a tendency for a change to occur →the affected area may become partially reduced in size by peripheral ossification →bone or cementum forms either as a single mass which enlarges by aggregation at its margin or as several masses →this mass either enlarges individually or they fuse →the fibrous tissue may be replaced entirely by bone of greater density than that of normal bone →once cementum is formed it remains unchanged without any reduction.

Clinical Features

- *Age and sex distribution*—it occurs during the middle age with a mean age of 39 years. Male to female ratio is 1:9 and is three times more common in blacks than in whites.
- *Site*—mandibular anterior region is commonly affected. Single area of one jaw may be involved or the greater part or both the jaws is affected.
- *Symptoms*—involved teeth are vital with no history of pain or sensitivity. Occasional lesions localize near the mental foramen and impinge on the mental nerve and produce pain, paresthesia or even anesthesia.
- *Signs*—hypercementosis is usually associated with it. It rarely enlarges.

Radiographic Features

- *Site*—it usually lies at the apex of the tooth. In rare cases, epicenter is high and over the apical thirds of the root. In most cases, lesion is multiple and bilateral.
- *Margins*—margins are well defined. A radiolucent border of varying width, surrounded by band of sclerotic bone is seen. Sclerotic bone represents immediate reaction of surrounding bone.
- *Stage I—Radiolucent (fibrous)*
 - *Radiodensity*—since there is loss of bony substance and replacement by connective tissue, the lesions appear radiolucent.
 - *Shape*—there is formation of a circumscribed area of periapical fibrosis accompanied by localized bone destruction (Fig. 14-28).

- *Margins*—the margins of the radiolucent area vary in different lesions; some are well defined but not corticated and others are poorly defined or well defined at one portion of the lesion and ill defined elsewhere. A rim of slightly denser bone surrounds the greater part or all the periphery of some lesion.
- *Lamina dura*—lamina dura around the tooth is lost.

Fig. 14-28: Early stage of PCD showing radiolucency at the periapical area of mandibular incisor.

- *Stage II—Mixed stage*
 - *Margins*—margins of the opacity are usually sharp but sometimes it can be ill defined and irregular.
 - *Internal structure*—minute radiopacities are seen within the radiolucent periapical area due to either bone or cementum formation (**Fig. 14-29**). It is called as *cementoblastic stage*. Small radiopacities may coalesce.
 - *Size*—opacity may vary from a millimeter or a centimeter or more.
 - *Shape*—it has round, oval or irregular shape.
- *Stage III—Radiopaque*
 - *Radiodensity*—there is complete opacification (**Fig. 14-30**).
 - *Appearance*—it appears as a well defined radiopacity usually bordered by a radiolucent capsule separating it from the adjacent bone.
 - *Margins*—margins may vary from well defined to poorly define.
 - *Lamina dura*—lamina dura of adjacent teeth may be discontinuous in the area of lesion.
 - *Hypercementosis*—hypercementosis is produced in some cases which can be seen at the apex.
 - *Effect on surrounding structures*—root resorption is rare. The lesion can elevate the floor of maxillary antrum.

Fig. 14-29: Mixed stage of PCD showing radiopacity in the radiolucency.

- Some of these large dense areas reveal small dark spot which resemble dense bone with persistent small marrow spaces.

Fig. 14-30: Mature stage of PCD showing complete radiopaque lesion.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Radiological diagnosis*—radiolucency at the apex of vital teeth with no loss of lamina dura in early stage. In the mature stage radiopaque lesion is seen.

- *Laboratory diagnosis*—biopsy shows periapical bone is replaced by mass of fibrous tissue. Small, round to ovoid calcifications are deposited within the fibrous tissue.

Differential Diagnosis

The osteolytic stage or early stage

- *Pulpo-periapical lesions*—are associated with pulpal disease and the involved tooth is sensitive to percussion. Any radiolucent area at the apex of the tooth, particularly lower incisor, which does not show caries or restoration, would be suspected periapical cemental dysplasia.
- *A traumatic bone cyst*—when projected over a tooth with a vital pulp can be confused with periapical cemental dysplasia; but it is usually much larger and is characteristically found in a younger age group.
- *The cementifying and ossifying fibroma in early stages*—it also occurs at the apex of vital teeth in early stages but it affects a younger age group and they have a potential to be a very large lesions. They do not have a predilection for the lower incisor area but occurs most often in the premolar region.
- *Cementoblastoma*—it can be confused in early stages but it is a rare lesion that occurs almost exclusively at the apex of mandibular molars. It extends higher on the root. It is connected to the root surface in mandibular premolar and molar area.

Intermediate stage/mixed stage

- *Malignant osteoblastic carcinoma*—it is rapidly growing with borders which are irregular and ill defined.
- *The intermediate stage of odontoma*—it shows orderly relationship of radiopaque enamel, dentin and pulp space in compound odontoma; while in cases of complex odontoma, more radiopaque component of enamel will give a clue towards the true identity of the lesion. In addition, odontoma is located above the crown of an unerupted tooth, sometimes between teeth, but rarely in the periapical region.
- *Calcifying crown*—it presents in the 1st and 2nd decade and is easily identified by their anticipated location in the jaw and the presence of a similar picture in the contralateral jaw.
- *Fibrous dysplasia*—it occurs in a younger age group (10-20 years) than periapical cemental dysplasia and is common in the maxilla. Margins are poorly defined in fibrous dysplasia and well defined in periapical cemental dysplasia.
- *Periapical rarefying osteitis*—is seen with non-vital teeth. Absence of pain, tenderness on palpation, inflammation and no regional lymphadenopathy favors the diagnosis of periapical cemental dysplasia.
- *Cementifying and ossifying fibroma*—periapical cemental dysplasia is a common lesion as compared to

cementifying and ossifying fibroma. Periapical cemental dysplasia has a predilection for lower incisors while cementifying and ossifying fibroma is common in the premolar- molar region. Periapical cemental dysplasia occurs in a younger age group as compared to cementifying and ossifying fibroma. Periapical cemental dysplasia seldom attains a diameter above 1 cm while cementifying and ossifying fibroma attains a diameter of 2-4 centimeters.

Mature stage/radiopaque

- *Hypercementosis*—it involves anterior teeth and is attached to a part of the root and is separated from periapical bone by the radiolucent periodontal ligament space which surrounds the entire root.
- *Condensing osteitis*—it occurs at the apices of non-vital teeth whereas periapical cemental dysplasia does not. In addition, condensing osteitis does not have a radiolucent rim whereas it is present in periapical cemental dysplasia.
- *Periapical idiopathic osteosclerosis*—it may be difficult to differentiate because both occur in the periapex of healthy teeth with vital pulp. Periapical cemental dysplasia is smoothly contoured and almost always round or ovoid whereas periapical idiopathic osteosclerosis is usually quite irregular in shape and also there is absence of the radiolucent rim.
- *Paget's disease and osteoblastic metastatic carcinoma*—can be ruled out if there is absence of systemic symptoms.

Management

- *Continuous observation*—it requires continuous observation and subsequent verification through periodic radiographic examination.
- *Surgical enucleation*—surgical enucleation is indicated for larger lesions which have caused expansion of the cortical plates or when the clinician is unsure of the working diagnosis.

Benign Cementoblastoma

The benign cementoblastoma is also called as *true cementoma*. It is rare odontogenic tumor representing less than 1% of all odontogenic tumors.

Norberg initially described it in 1930 and defined as a true neoplasm of cementum or cementum-like tissue that formed on a tooth root by cementoblasts.

The WHO defines the benign cementoblastoma as 'a neoplasm' characterized by the formation of sheds of cementum-like tissue which may contain a very large number of reversal line and may be unmineralized at the periphery of the mass or in the more active growth areas.

The accepted theory of its origin is that it is a mesenchymal odontogenic tumor. The cementoblastoma's

precise derivation is connective tissue of the periodontal ligament.

Clinical Features

- *Age and sex distribution*—the benign cementoblastoma occurs most frequently under the age of 25 years and there appears to be a slight predilection for males.
- *Site*—cementoblastoma can occur in both maxilla and the mandible. The mandible, however, is involved three times more frequently than maxilla. The mandibular first permanent molar is the most frequently affected tooth.
- *Symptoms*—pain is frequently present and it is the most common symptom.
- *Sign*—the associated tooth is vital unless coincidentally involved. The lesion is slow growing and produces cortical expansion. Extraoral (**Fig. 14-31**) and intraoral swelling can also be present (**Fig. 14-32**).

Fig. 14-31: Swelling of the jaw seen extraorally due to cementoblastoma

Fig. 14-32: Cementoblastoma intraoral view showing intraoral swelling.

Radiographic Features

- *Margins*—well defined radiopacities usually attached to the roots of premolars and molars surrounded at the border by a radiolucent halo are seen.
- *Appearance*—the radiological appearance of the cementoblastoma is highly characteristic, seen as circular radiopaque mass attached to the root of the one or more teeth. A narrow radiolucent zone surrounds the lesion and delineates from adjacent bone (**Fig. 14-33**).
- *Root outline*—the outline of the affected root is generally obliterated because of resorption of the root and fusion of the mass to the tooth.
- *Internal structure*—they are mixed radiolucent-radiopaque lesion that may be amorphous or may have *wheel-like spoke pattern*. Density of cementum obscures the outline of the enveloped root.
- *Effect on surrounding structures*—the outline of the tooth is obliterated because of resorption of the root and fusion of the mass to the tooth.
- *Expansion*—occlusal radiograph will demonstrate its expansive nature.

Fig. 14-33: Benign cementoblastoma showing radiopacity surrounded by radiolucent capsule.

Diagnosis

- *Clinical diagnosis*—not so specific
- *Radiological diagnosis*—radiopaque lesion surrounded by radiolucent capsule attached to root surface is typical of cementoblastoma.
- *Laboratory diagnosis*—biopsy shows cementum-like tissue, deposited in globular pattern resembling giant cementicles.

Differential Diagnosis

- *Periapical cemental dysplasia*—there is no expansion of the jaws and females are more commonly affected.
- *Chronic focal sclerosing osteomyelitis*—no radiolucent halo is present.
- *Periapical osteosclerosis*—radiolucent halo present in case of cementoblastoma and it is absent in periapical osteosclerosis.

- *Hypercementosis*—cementoblastoma initially associated with larger root than hypercementosis and is surrounded by radiolucent halo.

Management

- *Excision*—the recommended treatment of cementoblastoma usually consists of the surgical extraction of the tooth together with the attached calcified mass. Surgical excision of the mass with root amputation and endodontic treatment of the involved tooth may be considered. The prognosis is excellent and the tumor does not recur after total removal. Recurrence is not seen.
- *Endodontic treatment*—tumor can be amputated from the tooth and tooth is then endodontically treated.

Ameloblastic Fibro-odontoma

The name is applied to an odontogenic lesion that exhibits features of ameloblastic fibroma as well as dentin and enamel. It is mixed epithelial-mesenchymal proliferation and both mature and immature areas.

Clinical Features

- *Age and sex*—it is usually seen in a young age group with mean age of occurrence of 12 years. Males are more commonly affected than females.
- *Site*—maxilla and mandible are equally affected. In mandible, it occurs in the molar area and in the maxilla it usually involves the maxillary sinus.
- *Symptoms*—the most common presenting complaint is swelling and failure of tooth eruption. The maxillary tumor if large interferes with nasal respiration, eating and speech.
- *Signs*—ameloblastic fibro-odontoma consists of elements of ameloblastic odontoma and is more aggressive than the common odontoma.

Radiological Features

- *Radiodensity*—a well-circumscribed lesion presenting as an expansile radiolucency generally containing either a solitary radiopaque mass or multiple small opacities representing the odontoma portion of the lesion (**Fig. 14-34**).
- *Size*—some of the lesions are relatively small, not over 1 to 2 cm in diameter; while others may be exceedingly large involving a considerable portion of the body of mandible and extending in the ramus.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Radiological diagnosis*—radiopaque calcified mass in the radiolucent defect.

Fig. 14-34: Radiolucent defect showing radiopaque structure representing ameloblastic fibro-odontoma (Courtesy Dr Parate).

- *Laboratory diagnosis*—biopsy shows epithelial component with dysplastic dentin. There are cords, fingers, strands and rosettes of primitive odontogenic columnar or cuboidal epithelial cells often resembling dental lamina. The mesenchymal component is an embryonic fibrous connective tissue with delicate fibrils interspersed by large primitive fibroblast all resembling dental papilla.

Management

- *Curettage*—it is treated by curettage since it does not appear to locally invade the bone.

Ameloblastic Odontoma

It is also called as 'odontoameloblastoma'. It is characterized by the simultaneous occurrence of an ameloblastoma and a composite odontome. It is extremely rare odontogenic tumor.

Clinical Features

- *Age*—it occurs in children early in the second decade of life.
- *Site*—greater incidence in mandible as compared to maxilla.
- *Symptoms*—it produces considerable facial deformity or asymmetry if left untreated. Mild pain may be present as well as delayed eruption of teeth also occurs.
- *Sign*—it causes bony expansion and destruction of the cortex and displacement of teeth.

Radiological Features

- *Radiodensity*—radiographic density of ameloblastic odontoma may be radiopaque and similar to the complex odontoma or may be mixed.
- *Internal structure*—there is presence of numerous small radiopaque masses (**Fig. 14-35**) which may or may not bear resemblance to the formed albeit miniature teeth. In

Fig. 14-35: Large masses of calcified structure seen in ameloblastic odontoma (Courtesy Dr Parate).

some cases, there is only a single irregular radiopaque mass of calcified tissue present.

- **Margins**—are well defined, uniformly smooth and with even border.
- **Cortical plate**—central destruction of bone with expansion of the cortical plates is prominent.
- **Effect on surrounding structures**—it can cause bone expansion, destruction and tooth displacement may occur.

Diagnosis

- **Clinical diagnosis**—not so specific.
- **Radiological diagnosis**—radiopaque calcified mass with cortical destruction.
- **Laboratory diagnosis**—biopsy shows undifferentiated epithelial cells with ameloblasts, enamel and enamel matrix, dentin, osteodentin, dentinoid and osteoid material. There is presence of sheets of typical ameloblastoma of one or the other of the recognized types usually basal cells, follicular or plexiform cells.

Management

- **Same as that of ameloblastoma**—tumor appears to have the same recurrence potential as an ameloblastoma and therefore should be treated similarly.

Malignant Tumor

Ameloblastic Fibrosarcoma

It is the malignant counterpart of the ameloblastic fibroma in which mesenchymal elements has become malignant. It is also called as 'ameloblastic sarcoma'.

Clinical Features

- **Age and sex**—it is very rare and most frequently occurs in young adults with an average age of occurrence being

30 years. It is more commonly seen in males as compared to female.

- **Site**—it occurs more frequently in mandible as compared to maxilla.
- **Symptoms**—it is uniformly painful, generally grows readily and causes destruction of bone with loosening of teeth.
- **Sign**—there may be ulceration and bleeding of the overlying mucosa. Swelling is usually soft in consistency.

Radiological Features

- **Radiodensity**—there is severe bone destruction (**Fig. 14-36**).
- **Margins**—it has irregular and poorly defined margins.
- **Effect on cortical bone**—there may be gross expansion and thinning of cortical bone.
- **Maxillary lesion**—in maxillary lesions, the involvement of the antrum may occur.

Fig. 14-36: Ameloblastic fibrosarcoma showing severe bone destruction.

Diagnosis

- **Clinical diagnosis**—not so specific.
- **Radiological diagnosis**—irregular bone destruction with ill defined margin can give clue to the diagnosis.
- **Laboratory diagnosis**—mesenchymal tissue exhibits a remarkable increase in cellularity; the malignant fibroblast being bizarre and pleomorphic with hyperchromatic nuclei and numerous atypical mitotic figures.

Management

- **Radical resection**—hemimandibulectomy or hemimaxillectomy can be done in patient of ameloblastic fibrosarcoma. Recurrence is common and prognosis is poor.

Ameloblastic Odontosarcoma

It is similar to ameloblastic fibrosarcoma but limited amounts of dysplastic dentin and enamel are formed.

Malignant Ameloblastoma and Ameloblastic Carcinoma

It is a rare type of tumor and diagnosis depends upon presence of metastases, which in some cases is seen in lymph nodes and lungs.

Terminology

- *Malignant ameloblastoma*—are those ameloblastomas that metastasize but in which the metastatic lesion do not show any histological difference from the primary tumor.
- *Ameloblastic carcinoma*—shows obvious histological malignant transformation but the metastatic lesions do not bear resemblance to the primary odontogenic tumor.

Clinical Features

- *Age and sex*—males are affected more commonly than females. It occurs in 1st to 6th decade with mean age of diagnosis 28-32 years.
- *Site*—it is almost exclusively seen in the mandible.
- *Symptoms*—swelling followed by pain and/or rapid growth.
- *Sign*—teeth may be displaced and loosened. Tenderness of overlying soft tissue is present.
- *Sites for metastasis*—lungs, spleen, kidney, lymph nodes and ileum.
- *Local extension*—it may occur in adjacent bone, connective tissue or salivary gland.

Radiological Features

- *Site*—it is more common in premolar-molar area of mandible.
- *Margin*—it has well defined border with cortication, presence of crenations or scalloping in the perimeter. There may be loss of cortical boundary and breaching of the cortical boundary with soft tissue spread (**Figs 14.37A and B**).
- *Appearance*—it is either unilocular or multilocular giving the appearance of honeycomb or soap bubble pattern. Most of the septa are robust and thick.
- *Effect on surrounding structure*—teeth may be displaced and may exhibit root resorption. Lamina dura may be lost. Bony borders may be effaced or breached. The mandibular neurovascular canal may be displaced or eroded.

Differential Diagnosis

- *Benign ameloblastoma*—in it, there is no evidence of metastasis in benign ameloblastoma.
- *Central giant cell granuloma*—if the lesion is anterior to the premolar, central giant cell granuloma should be suspected.

Figs 14.37A and B: Malignant ameloblastoma showing loss of cortical boundary (Courtesy Dr Iswar).

- *Malignant changes in odontogenic cyst*—if the lesion is locally invasive and it is apparent radiologically then malignant changes in odontogenic cyst should be suspected.
- *Odontogenic myxoma*—there is missing tooth associated with it.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Radiological diagnosis*—loss of cortical boundary with features suggestive of ameloblastoma.
- *Laboratory diagnosis*—there may be cytological features of malignancy.

Management

- *En block resection*—it is treated with en bloc resection. Prognosis is poor in this case.
- *Pulmonary metastasis*—radiation therapy and chemotherapy for pulmonary metastasis.

Primary Intraosseous Carcinoma

It is also called as 'central mandibular carcinoma', 'primary intra-osseous carcinoma', 'primary epithelial tumor of the jaw', 'primary intra-alveolar epidermoid carcinoma' and 'central squamous cell carcinoma'. It develops within the depth of the jaw. It is rare and may remain silent until they have reached a fairly large size.

Origin

- *Malignant transformation*—primary intraosseous carcinoma may occur from malignant transformation of epithelial lining of odontogenic or non-odontogenic cyst, or ameloblastoma by metastases from different sites.
- *Primary tumor of maxillary sinus*—in case of maxilla, it may arise from primary tumor of the maxillary sinus.
- *Cell rests of odontogenic epithelium*—the tumor arises from the cell rests of the odontogenic epithelium or from the epithelial remnants at the site of fusion between two embryonic processes.
- *Cells of dental lamina*—in normal situation for some of the original cells of the dental lamina or enamel organ to remain in the jaw long after the function of these cells are completed. Malignant tumor may develop from these cells.

Types

- Those arising from odontogenic cysts.
- Those arising from ameloblastoma either well differentiated (malignant ameloblastoma) or poorly differentiated (ameloblastic carcinoma).
- Those arising de novo from odontogenic epithelium residues, either keratinizing or non-keratinizing.

Clinical Features

- *Age and sex distribution*—there is a wide range of age distribution with majority of cases occurring in 6th and 7th decade of life. It is more common in males than in females with a ratio of 2:1 and more common in mandible than in maxilla.
- *Symptoms*—the early symptom is swelling of the jaw with pain and mobility of the teeth before ulceration has occurred. Pathological fracture and lip paresthesia also occurs.
- *Signs*—there is rapid expansion and destruction of jaw bones. Tumor invades the periodontal ligament and the alveolar bone, destroying it. There may be lymphadenopathy. Surface epithelium is normal. Occasionally, the pulp of the teeth may be invaded by neoplasm. Perforation of cortical plate may occur.
- *Non-healing socket*—extraction of teeth result in non-healing socket and sometimes tumor may protrude from the non-healed socket.

Radiological Features

- *Radiodensity*—it presents as a diffuse radiolucency similar to other central malignant neoplasms of the jaws.
- *Site*—mandible is more commonly involved than the maxilla. Molar region is frequently involved than the anterior region.
- *Appearance*—central squamous cell carcinoma is very rare and appears as more or less rounded radiolucency completely surrounded by bone.
- *Margin*—its borders become ragged and there is no evidence of bone formation within the tumor.
- *Shape*—they are more often rounded or irregular in shape (Fig. 14-38). The purely lytic but irregular extension of the tumor may leave some areas of residual bone, either in the shape of islands or strands.

Fig. 14-38: Irregular radiolucency seen in mandible of intraosseous carcinoma.

- *Effect on surrounding structures*—there is expansion and distortion of the cortical plates of the jaw bone. They may cause destruction of the antral or nasal flows, loss of cortical outline of the mandibular neurovascular canal and effacement of the lamina dura.
- *Teeth*—teeth that lose both lamina dura and supporting bone appear to be floating in space.
- *Cortical plate and alveolar bone*—there may be perforation of the cortical plate and pathological fracture. There is severe destruction of alveolar bone with displacement of the teeth.

Diagnosis

- *Clinical diagnosis*—rapid expansion, lymphadenopathy, and pathological fracture may suspect this disease.
- *Radiological diagnosis*—it is purely lytic lesion with expansion and destruction of cortical plate.

- *Laboratory diagnosis*—biopsy shows plexiform pattern of peripheral cells of the tumor masses showing palisading arrangement, thereby resembling odontogenic epithelium. The tumor cells themselves generally exhibit nuclear pleomorphism and hyperchromatism, mitotic activity.

Differential Diagnosis

- *Periapical cyst or granulomas*—if the lesion is not aggressive, it may be mistaken for periapical cyst or granulomas. But in periapical cyst, tooth is non-vital and borders are well defined.
- *Odontogenic tumors*—margins are usually well defined as compared to carcinoma.
- *Metastatic carcinoma*—if the margins are obviously infiltrative with extensive bone destruction, it will be intraosseous carcinoma.
- *Peripheral squamous cell carcinoma*—surface epithelium is involved in peripheral squamous cell carcinoma.

Management

- *Surgical resection*—it is treatment of choice in primary intraosseous carcinoma.

Malignant Changes in Odontogenic Cyst

It is also called as '*carcinoma ex odontogenic cyst*'. It is uncommon lesion seen in oral cavity. There are carcinomatous changes found in odontogenic cyst. In some cases adjacent carcinoma may involve otherwise unrelated cyst. It occurs due to epithelial dysplasia occurring in the cyst lining.

Clinical Features

- *Age and sex distribution*—these are more commonly found in older patient with male predilection.
- *Site*—it can affect any cyst in the jaw. But keratocyst is more likely to undergo malignant changes than other cysts.
- *Symptoms*—the most common complaint is pain, which is dull and of several months duration. If upper jaw is involved, sinus pain and swelling may be present.
- *Sign*—pathological fracture, fistula formation and regional lymphadenopathy may occur.

Radiological Features

- *Site*—it is most commonly found in tooth bearing area of the jaw. Most commonly in the mandible.
- *Margin*—if it is small lesion in the cyst wall, the periphery may be well defined and corticated. As the malignant lesion progressively replaces cyst lining, the smooth border is lost or becomes ill defined. Advanced lesion

has an ill defined, infiltrative periphery that lacks any cortication.

- *Shape*—in initial lesion, the shape is ovoid or round. In advanced lesion, shape becomes less '*hydraulic*' looking and more diffuse.
- *Radiodensity*—it is more radiolucent than invasive surface carcinoma.
- *Effect on surrounding structure*—there is thinning and destruction of lamina dura of adjacent teeth. It can also destroy adjacent cortical boundaries such as inferior border of the jaw or floor of nose. It can produce complete destruction of the alveolar process.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—smoothness of cyst is lost and margin becoming ill defined may give clue to the diagnosis.
- *Laboratory diagnosis*—they are same as that of squamous cell carcinoma.

Differential Diagnosis

- *Infected dental cyst*—if dental cyst is infected, it may lose its normal cortical boundary and appear to be ragged. But infected cyst usually shows a reactive peripheral sclerosis because of inflammatory products present in the cystic lumen.
- *Metastatic tumor*—it is multifocal and there is history of primary tumor.
- *Multiple myeloma*—multiple separate radiolucency can be seen.

Management

- *Radical resection*—treatment given is either local block excision or radical resection.

Odontogenic Fibrosarcoma

It is the malignant counterpart of odontogenic fibroma. It originates from same mesenchymal tissue, as same in central fibroma.

Clinical Features

It is a destructive lesion which produces a fleshy, bulky growth. It is asymptomatic but pain may be present in many cases.

Diagnosis

Biopsy shows cellular element that may or may not be prominent than the fibrillar component. The cells often exhibit considerable mitotic activity. They resemble imma-

ture fibroblasts and appear as elongated cells containing ovoid nuclei with varying degree of pleomorphism and are situated in a fibrous meshwork which may or may not exhibit foci of odontogenic epithelium.

Management

Radical surgical removal with resection of the jaw. Prognosis is poor.

Clear Cell Odontogenic Tumor or Carcinoma

It is rare odontogenic tumor with potential for lymphatic or pulmonary metastases. Its origin is unknown, but ultrastructural study shows clear cells, which have similarities to glycogen rich presecretory ameloblasts.

Clinical Features

- *Age and sex*—most cases reported in women over 60 years of age.
- *Site*—both maxilla and mandible have been involved.
- *Symptoms*—it may present as asymptomatic or painful bony swelling.

Radiological Features

- *Appearance*—unilocular or multilocular radiolucency with ill defined margins.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—not specific.
- *Laboratory diagnosis*—biopsy shows nests of epithelial cells with clear or faintly eosinophilic cytoplasm which is separated by thin strands of hyalinized material.

Management

- *Extensive resection*—tumors demonstrate aggressive local behavior and potential lymphatic and pulmonary metastases and therefore should be treated with extensive resection.

Introduction

It is a new growth representing the tissue of origin. The study of the tumors of the oral cavity and adjacent tissues constitute an important phase of dentistry because of the role of a dentist in the diagnosis of the lesion.

Characteristics of Benign Tumor

- *Insidious onset*—it has got insidious onset and the rate of growth is generally slow and is for a longer period of time.
- *Well defined mass*—it has got well defined mass of regular smooth outline and it possesses a fibrous capsule.
- *Symptoms*—benign tumors usually produce symptoms due to the swelling and pressure effect on the surrounding structures. It is usually painless and they never metastasize.
- *Small*—benign tumors are smaller, as compared to malignant tumors.
- *Displacement of teeth*—there is displacement of adjacent normal tissues.

Terminology

- *Hamartomas*—it is an abnormal proliferation of normal tissue at its usual location. For e.g. Hemangioma.
- *Neoplasm*—tumors that continue to grow indefinitely are called as neoplasm.
- *Hypertrophy*—enlargement caused by an increase in the size of cells.
- *Hypertrophy*—enlargement caused by an increase in the number of the cells.

Classification

Epithelial tissue

- Papilloma

- Keratoacanthoma
- Squamous acanthoma
- Nevus

Fibrous connective tissue

- Fibroma
- Fibrous hyperplasia
- Fibrous epulis
- Giant cell fibroma
- Fibrous histiocytomas
- Desmoplastic fibroma
- Myxoma
- Myxofibroma

Cartilage tissue

- Chondroma
- Chondroblastoma
- Chondromyxoid fibroma

Adipose tissue

- Lipoma
- Angiolipoma

Bone

- Osteoma
- Osteoid osteoma
- Osteoblastoma
- Exostosis-tori-torus palatinus-torus mandibularis
- Osteomatosis

Vascular tissue

- Hemangioma
- Hereditary hemorrhagic telangiectasia
- Lymphangioma
- Arteriovenous fistula
- Glomus tumor

Neural tissue

- Neurofibroma
- Neurolemmoma

- Schwannoma
- Ganglioneuroma
- Traumatic neuroma
- Melanotic neuroectodermal tumor of infancy

Muscles

- Leiomyoma
- Rhabdomyoma
- Granular cell myoblastoma

Giant cell tumor

- Central and peripheral giant cell tumor
- Giant cell granuloma
- Giant cell tumor of hyperthyroidism

Teratoma

Tumors of Epithelial Origin

Papilloma

It is relatively a common, benign neoplasm of unknown origin, which arises from the surface of stratified squamous epithelium. It may be caused by papilloma virus.

Types

- *Squamous cell papilloma*—it may arise in the tongue, cheek, lip and esophagus
 - *Congenital*—it is usually present since birth.
 - *Infective*—it arises from viral infection.
 - *Soft papilloma*—it is often seen in eyelids of elderly people.
 - *Keratin horns*—it is due to excess keratin formation and seen in older people.
- *Basal cell papilloma*—it is also called as 'seborrheic or senile wart'. It occurs on the trunk, face, arms and armpits.

Clinical Features

- *Age*—average age of occurrence is in the 3rd and 4th decade of life, only 20% of cases are found below 20 years of age.
- *Common sites*—it is most commonly seen on tongue, palate, buccal mucosa, gingiva, lip, mandibular ridge and floor of mouth.
- *Cauliflower appearance*—it is typically an exophytic lesion with a cauliflower-like surface or with finger-like projection (Fig. 15-1). Projections are pointed or blunt. This appearance is caused by presence of deep clefts that extend well into lesion from the surface.
- *Base*—it generally arises from a pedunculated base. Some time, base may be broad rather than pedunculated.
- *Shape*—small mass on mucosa with a papillomatous shape.

- *Size*—the size of tumor may vary from 2 millimeters but it is seldom larger than 2 centimeters.
- *Color*—tumor with much keratinization is white and lesion without much keratinization is grayish pink in color.
- *Consistency*—tumor is firm, when keratinized and soft when it is non-keratinized.
- *Focal dermal hypoplasia syndrome*—in it, there are multiple oral papillomas, dermal hypoplasia and syndactyly with fatty herniation, coloboma and strabismus.
- *Other syndromes associated*—other syndromes in which multiple papillomas may occur are Cowden's syndrome, Down's syndrome and nevus unius lateris syndrome.

Fig. 15-1: Papilloma seen on palate as a white projection (Courtesy Dr Parate).

Diagnosis

- *Clinical diagnosis*—white cauliflower-like projection in oral cavity favors the diagnosis of papillomas.
- *Laboratory diagnosis*—histopathologically it consists of many long, thin, finger-like projections extending from the epithelium.

Differential Diagnosis

- *Verruca vulgaris*—common in skin and always has a sessile base.
- *Papillary squamous cell carcinoma*—base is not pedunculated. It grows rapidly and exceeds 0.5 to 2 cm in size.
- *Verrucous carcinoma*—seen at the age of 60 and 70 years and is associated with smoking and chewing tobacco or snuff, the mass is wider than the surface area with the base almost as wide as the lesion. It does not achieve much vertical length.
- *Condyloma latum and acuminatum*—they are less common and patient has a history of oral sex.

- *Pseudoepitheliomatous hyperplasia*—it has got sessile base.
- *Verruciform xanthoma*—rare in the oral cavity, has a broad base and vertical projections are minimum.

Management

- *Surgical excision*—elliptic incision on the tissue underlying the lesion should be given. Incision should be from the base of mucosa, into which the pedicle or stalk is inserted. If the tumor is properly excised, recurrence is rare.
- *Other modalities*—application of formaldehyde at night on the wart may cure the condition. Sometimes, silver nitrate application also cures the condition.

Verruciform Xanthoma

It is also called as 'Histiocytosis Y'. It is a papillomatous lesion of oral cavity in which accumulation of lipid laden histiocytes occur below the epithelium. The lesion occurs as an unusual reaction to localized epithelial trauma or damage.

Clinical Features

- *Age and sex*—there is strong female predilection and is usually seen in middle age.
- *Site*—it can occur at any site and is most frequently found on the gingiva or alveolar ridge, followed by the buccal mucosa, palate, floor of the mouth, lip and lower mucobuccal fold.
- *Verruciform appearance*—the lesion appears as soft, well demarcated slightly elevated mass with white, yellowish white or red in color. It has got papillary or roughened appearance which is called as verruciform appearance.
- *Crateriform surface*—in some cases, crateriform surface have also been reported.
- *Base*—it is either sessile or has a pedunculated base.
- *Size*—it may be as small as 2 mm to as large as 1.5 cm.

Diagnosis

- *Clinical diagnosis*—the lesion has got verruciform surface and it is usually solitary.
- *Laboratory diagnosis*—biopsy will show large swollen foam cells or *xanthoma* cells, which are presumably histiocytes.

Management

- *Surgical excision*—it is treated with conservative surgical excision.

Keratoacanthoma

It is also called as 'self healing carcinoma', 'molluscum sebaceum', and 'pseudocarcinoma'. It, clinically and

histologically, resembles epidermoid carcinoma and it is frequently mistaken as cancer. It is believed to arise from hair follicles.

Etiology

- *Genetic*—there seems to be hereditary predisposition for the multiple lesions.
- *Viral*—human papillomavirus possible subtypes HPV 26 or HPV 37 have been associated with Keratoacanthoma.
- *Sun exposure*—sun exposure is also one of the etiological factors as it is more commonly seen on sun exposed skin.
- *Chemical*—chemical agents such as coal tar and mineral oil has been associated with Keratoacanthoma in some cases.
- *Trauma*—association of trauma with Keratoacanthoma has been controversial.

Types

- *Ferguson Smith type*—there are large number of keratoacanthoma which is hereditary in nature.
- *Eruptive Grazybowski type*—in this, there are hundreds of small papules on skin and upper digestive tract.

Clinical Features

- *Age and sex*—male to female ratio is 2:1 and majority of cases occur between the ages of 50 to 70 years.
- *Common site*—exposed skin including cheeks, nose and dorsum of the hands. Intraoral lesion is uncommon; if found, is more common on lips.
- *Symptoms*—the lesion is often painful and regional lymphadenopathy may be present.
- *Appearance*—the lesion appears as an elevated umbilicated or crateriform with depressed central core which represent a plug of keratin. Lesion appear to be fixed to surrounding tissue.
- *Shape*—it appears as dome shaped.
- *Color of keratin plug*—keratin pit is frequently discolored, being yellowish brown in color.
- *Lip*—on the lower lip, the lesion shows smooth, raised, rolled borders with a central plug of hard keratin.
- *Margins*—margins are sharply delineated. There may be elevation of the rolled margins.
- *Size*—it grows to maximum size of 1 to 2 cm in diameter.
- *Progress*—it begins as small, firm nodules that develop to full size over a period of four to eight weeks and persist as static lesions for another 4 to 8 weeks. After that, it undergoes spontaneous regression over the next six to eight weeks period by expulsion of the keratin core with resorption of the mass. There may be unsightly scar formation.

- *Muir-Torre syndrome*—it consists of sebaceous neoplasms, keratoacanthoma and gastrointestinal carcinomas.

Diagnosis

- *Clinical diagnosis*—elevated lesion with central keratin plug on sun exposed skin will aid in diagnosis of keratoacanthoma.
- *Laboratory diagnosis*—on biopsy there is thickened layer of parakeratin or orthokeratin with central plugging.

Differential Diagnosis

- *Keratinizing squamous cell carcinoma*—cancerous lesion usually fails to exhibit a smooth round regularity, which is present in keratoacanthoma.
- *Warty dyskeratoma*—is usually small, i.e. less than 0.5 cm, as compared to keratoacanthoma which can attain a dimension of 1-2 cm.

Management

- *Surgical excision*—it often resolves spontaneously without treatment. The lesion may be treated by surgical excision as the scar remaining from excision will be more cosmetic than that resulting from spontaneous regression.

Benign Melanocytic Nevus

It is also called as 'pigmented mole'. Pigmented nevus is a superficial lesion composed of so called nevus cells; hence the term 'cellular nevus'. Nevus is defined as a congenital, developmental tumor like malformation of the skin or mucous membrane.

Types

- *Congenital melanocytic nevus*—These are nevus which are present at birth. Around 15% of congenital nevi is found in head and neck region.
- *Acquired melanocytic nevus (common mole)*—it is present later in life
 - Intradermal nevus
 - Junctional nevus
 - Compound nevus
- *Halo nevus*—it results from nevus cell destruction by immune system.
- *Blue nevus (Jadassohn-Tieche nevus, dermal melanocytoma)*—benign proliferation of dermal melanocytes deep in subepithelial connective tissue.
- *Spitz nevus (benign juvenile melanoma, spindle and epithelioid cell nevus)*—it shares histological features with melanoma. This lesion was described by Spitz in 1948.

Clinical Features

Congenital melanocytic nevus

- *Site*—it is more commonly seen in head and neck region. Intraoral involvement is rare congenital form.
- *Small congenital nevi*—they are greater than 1 cm in diameter and less than 20 cm in diameter.
- *Large nevi*—they are greater than 20 cm in diameter and can cover larger areas of the skin.
- *Appearance*—lesion appear as brown to black plaque with rough surface (**Fig. 15-2**). Early lesion is flat and dark tan which later on becomes elevated, nodular and rougher.
- *Hypertrichosis*—there is presence of excess hair within the lesion. These hairs become prominent with the age giving the appearance of giant hairy nevus.
- *Bathing trunk nevus or garment nevus*—a very large congenital nevus is termed as bathing trunk nevus or garment nevus as patient gives appearance of wearing an article of clothing.

Fig. 15-2: Congenital nevi presented as brown plaque with rough surface.

Acquired melanocytic nevus

- *Age and sex distribution*—acquired nevi are extremely common and appear at 8th month of life and increases in number with age, apparently reaching their peak numerically in the late third decade of life.
- *Site*—it is seen occasionally in the oral cavity, but frequently on the skin. Most of the lesions are seen above the waist. Head and neck are the common site of involvement.
- *Junctional nevus*—this is the earliest presentation of nevus. This name is derived from its location as these are situated in basal layer just above junction of epidermis and dermis. They are flat, demarcated, and brown to black macule. They have regular, oval and round outline.

Fig. 15-3: Compound nevus showing brown elevated lesion above the upper lip.

- **Compound nevus (Fig. 15-3)**—these are slightly elevated, soft papule with smooth surface. The lesion is composed of two parts intradermal and junctional nevus. The degree of pigmentation becomes less with lesion appearing brown or tan.
- **Intradermal nevi**—it may be smooth flat lesion or may be elevated above the surface. It may or may not exhibit brown pigmentation and it often shows strands of hair growing from the surface (**Fig. 15-4**). It is firm on palpation and are raised above the surface. Ulceration is uncommon unless nevi are situated in belt or bra strap area.
- **Intraoral nevi**—intraorally nevus can occur at any site but most commonly occur on hard palate, buccal mucosa, lip, and in gingiva. Most nevi present as raised, macular lesions, but some are flat and macular. Intraoral nevi are slow growing and their size is usually less than 1 cm in diameter.

Fig. 15-4: Intradermal nevi showing growing hair from surface.

Halo nevus

- **Site**—it is most commonly seen on skin of trunk.
- **Age**—it is seen in second decade of life.
- **Appearance**—there is central pigmented papule or macule surrounded by zone of hypopigmentation. This zone of hypopigmentation occurs due to destruction of nevus cell by immune system.

Spitz nevus (benign juvenile melanoma, spindle cell or epithelioid cell nevus)

- **Age**—it occurs in children.
- **Site**—it is more commonly seen on the skin of extremities of face.
- **Appearance**—it appears as solitary, dome shaped, pink to reddish brown papule.
- **Size**—it is usually smaller than 6 mm in diameter.

Blue nevus (dermal melanocytoma, Jadassohn-Tieche nevus)

- **Age**—The majority of blue nevi are present at birth and in early childhood. They remain unchanged throughout the life.
- **Site**—it occurs chiefly on buttock, dorsum of the feet and hands, face and occasionally on other areas.
- **Appearance**—The lesions are smooth and exhibit hair growing from the surface.
- **Color**—the color of blue nevi occurs as melanocytes reside deep in the connective tissue and the overlying vessels dampen the brown coloration of melanin and thus yield a blue tint.
- **Intraoral nevi**—in the oral mucosa, they may be macular or nodular in appearance.

Diagnosis

- **Clinical diagnosis**—clinically, nevi can be diagnosed easily by their features.
- **Laboratory diagnosis**—nevus contain granules of melanin pigment in their cytoplasm. Epithelium is thin and irregular and shows “abtropfung” or “dropping off” effect.

Management

- **Surgical removal**—it has been customary to recommend the removal of pigmented mole if it occurs in areas where they are irritated by clothing, such as belt or collar line or if they suddenly begin to increase in size, deepen in color or become ulcerated.

Tumors of Fibrous Connective Tissue Origin

Fibroma

It is a benign soft tissue tumor found in the oral cavity. True benign neoplasm of the fibrous tissue is relatively an

infrequent lesion. Most of these lesions are infact hyperplasia or reactive proliferation of fibrous tissue. It develops due to chronic irritation.

Clinical Features

- *Age and sex distribution*—it can occur at any age but is common in 3rd, 4th and 5th decades. There is no sex predilection.
- *Site*—occurs on the gingiva, tongue, buccal mucosa and palate.
- *Symptoms*—they are usually painless, but if they are in a position where they can be bitten or injured, there may be pain and discomfort.
- *Appearance*—it is most often sessile, dome shaped or slightly pedunculated with smooth contour. The lesions on lips and tongue present as circumscribed nodules.
- *Signs*—tumor sometimes becomes irritated and inflamed and may show superficial ulceration.
- *Surface and color*—the color of tumor is pink and surface is smooth (Fig. 15-5). In some lesion may appear white due to continuous irritation (Fig. 15-6).

Fig. 15-5: Smooth surface pink nodule seen in fibroma of the patient (Courtesy Dr Bande).

Fig. 15-6: Whitish color of fibroma due to chronic irritation.

- *Size*—tumor may be very small or in rare instances may range up to several centimeters in diameter.
- *Consistency*—the consistency can range from soft and myxomatous to firm and elastic. According to the consistency the tumor is termed as 'hard fibroma' and 'soft fibroma'.

Diagnosis

- *Clinical diagnosis*—sessile, firm on palpation with pink color and smooth surface will go in favor of fibroma.
- *Laboratory diagnosis*—biopsy shows bundles of interlacing collagenous fibers interspersed with varying number of fibroblasts or fibrocytes and small blood vessels.

Differential Diagnosis

- *Lipofibroma*—feels softer on palpation.
- *Myxofibroma*—feels softer on palpation.

Management

- *Surgical excisions*—it is treated by conservative surgical excision.

Fibrous Hyperplasia

It is also called as 'inflammatory fibrous hyperplasia', 'denture injury tumor' and 'epulis fissuratum'.

Etiology

- *Ill fitting dentures*—it is the most common reaction to a chronically ill-fitting denture. It occurs due to overextended denture flanges.
- *Others*—other factors which are responsible are ragged margins of teeth, overhanging restorations, sharp spicules of bone, badly fitting clasps and chronic biting of cheek and lips.

Clinical Features

- *Site*—there is development of elongated rolls of tissue in the mucolabial or mucobuccal fold area, into which the denture flanges conveniently fit.
- *Appearance*—there may be small nodular or polypoid overgrowth of fibrous tissue due to gingival irritation.
- *Epulis fissuratum*—when the lesions occur in buccal sulcus due to denture flanges, it is called as epulis fissuratum (Figs 15-7 and 15-8). In it, there is concomitant overgrowth of surrounding fibrous tissues with a groove in it.
- *Signs*—the excess folds of tissue are not usually inflamed clinically, although there may be irritation or even ulceration in the base of the fold, into which the denture flange fits.

- **Consistency**—the lesion is firm on palpation.
- **Size**—the size of the lesion can be small to massive lesion which involves most of the length of the vestibule.
- **Leaf-like denture fibroma or fibroepithelial polyps**—this occurs beneath the denture in hard palate area. It is flattened pink mass with cupped out depression.

Fig. 15-7: Fibrous growth seen in buccal sulcus due to denture in upper tuberosity area (Courtesy Dr Parate).

Fig. 15-8: Fibrous overgrowth seen on the alveolar ridge due to denture.

Diagnosis

- **Clinical diagnosis**—fibrous growth in relation with denture flanges.
- **Laboratory diagnosis**—biopsy shows hyperplastic mass of tissue which is composed of an excessive bulk of fibrous connective tissue covered by a layer of stratified squamous epithelium, may be of normal thickness or show acanthosis.

Differential Diagnosis

- **Hemangioma**—it is present at birth.

- **Metastatic tumor**—there is history of primary tumor.
- **Papilloma**—white with cauliflower-like surface.

Management

- **Elimination of irritation**—elimination of irritation should be done.
- **Excisional biopsy**—it should be treated with excisional biopsy.

Fibrous Epulis

It is the term used when fibrous growth occurs in the gingiva. The possible cause of it is irritation from subgingival calculus or adjacent carious tooth.

Clinical Features

- **Age and sex distribution**—it is more common in females in the ratio of 4:1.
- **Site**—the interdental papilla of the gingiva is the commonest site.
- **Appearance**—the lesion forms a sessile (Fig. 15-9) or pedunculated mass covered by the mucous membrane.
- **Color**—it varies from normal tint to deep red, depending upon the vascularity and inflammatory changes.
- **Signs**—occasionally superficial ulceration can be seen.

Fig. 15-9: Sessile growth seen which arise from interdental papilla in fibrous epulis.

Management

- **Surgical excision**—lesions are excised with small amount of adjacent normal tissue.

Fibrous Histiocytoma

It is also called as 'fibroxanthoma' dermatofibroma, sclerosing hemangioma, and nodular subepithelial fibrosis. It may occur in dermis and rare in oral cavity.

Clinical Features

- *Age and sex*—it is common in young adults, with male predominance.
- *Site*—it is usually seen on dermis (**Fig. 15-10**). Most common site is the extremities where the lesion is called as dermatofibroma. Intraorally it is common on lips, tongue, buccal mucosa and palate.
- *Symptoms*—it is a painless mass.
- *Signs*—there is soft, non-tender, firm swelling of varying size. There is displacement of regional teeth. It is locally an aggressive tumor.

Fig. 15-10: Fibrous histiocytoma showing extraoral swelling.

Diagnosis

- *Clinical diagnosis*—dermal tumor with intraoral soft fibrous growth will go in favor of fibrous histiocytoma.
- *Laboratory diagnosis*—biopsy shows rich vascular growth, made up of histiocytes and collagen producing fibroblast-like cells, which are arranged in a *whorl* or *cartwheel* pattern.

Management

- *Surgical excision*—it can be done and recurrence is uncommon.

Desmoplastic Fibroma

It arises from the mesenchyme of bone. It is also called as 'aggressive fibromatosis'. It produces an abundant number of collagen fibers. It is thought to be counterpart of soft tissue fibromatosis.

Clinical Features

- *Age and sex*—it is most commonly occurs in 2nd decades of life. There is no sex predilection.

- *Site*—in oral cavity, it involves mandible more commonly than maxilla, usually at molar-ramus-angle area. In the skeletal, it involves humerus and tibia.
- *Symptoms*—swelling of the jaw and sometimes, pain and tenderness may be present. In some cases, there may be limited opening of mouth.
- *Signs*—buccal cortex is enlarged and more advanced lesions exhibit facial asymmetry.
- *Progress*—they are aggressive and proliferate rapidly.
- *Syndrome associated*—it may be associated with Gardner's syndrome.

Radiological Features

- *Site*—the most common site is ramus and posterior area of mandible.
- *Radiodensity*—it appears as well defined radiolucency, either unilocular or multilocular. The larger lesions appear to be multilocular with very coarse and thick septa. Smaller lesions are completely radiolucent.
- *Margin*—margin can be well defined or ill defined.
- *Extent*—it may perforate the cortex and infiltrate the adjacent tissues.
- *Teeth*—divergence of contiguous tooth roots is a common finding. In some cases, there may be root resorption.

Diagnosis

- *Clinical diagnosis*—not so specific lesion.
- *Radiological diagnosis*—it should be included in multilocular radiolucent lesion as a differential diagnosis.
- *Laboratory diagnosis*—biopsy shows cells which are small or uniform, plump, or both. The fibrous product is generally mature with thick, wavy collagen fibers arranged in fascicle. The collagen fibers are usually thin and delicate with fasciculation produce a 'herring bone' or 'chevron' or 'storiform' pattern.

Differential Diagnosis

- *Fibrosarcoma*—Coarse and irregular septa and sometimes straight septa are seen in desmoplastic fibroma.

Management

- *Surgical excision*—wide local excision is the treatment of choice in these cases.
- *Curettage*—small lesion is managed by through curettage.
- *Extraction*—involved teeth should be extracted.

Giant Cell Fibroma

It is a well described, benign hyperplastic lesion of oral mucosa. It is not associated with chronic irritation.

Clinical Features

- *Sex and age distribution*—no sex predilection and can occur at any age. It is slightly more prevalent in women.
- *Common sites*—gingiva followed by tongue, palate, buccal mucosa and lips.
- *Symptoms*—it is asymptomatic and may be present for several years.
- *Appearance*—it is usually small, raised, pedunculated, papillary lesion, less than 1 cm in diameter.

Diagnosis

- *Clinical diagnosis*—sessile, pedunculated nodule, less than 1 cm in diameter presence on tongue (**Fig. 15-11**) with no history of irritation will be giant cell fibroma.
- *Laboratory diagnosis*—in biopsy, there is presence of numerous, large stellate and multinucleated giant fibroblasts in the connective tissue, which makes up the bulk of the lesion.

Fig. 15-11: Giant cell fibroma less than 1 cm in diameter seen on tongue.

Management

- *Surgical excision*—surgical excision is done and recurrence is rare.

Myofibroma

This spindle cell tumor consists of myofibroblasts.

Clinical Features

- *Age*—it can occur at any age, but more commonly found in fourth decade of life.
- *Site*—it is more common in head and neck region. Common oral site are lips, cheeks, and tongue.
- *Appearance*—it is painless mass and it exhibits rapid enlargement.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Laboratory diagnosis*—biopsy shows interlacing bundles of spindle cells with tapered or blunt ended nuclei. Tumor cells are positive for smooth muscle stain.

Management

- *Surgical excision*—it is the treatment of choice.

Oral Focal Mucinosi

It is oral counterpart of cutaneous focal mucinosis. This lesion results from overproduction of hyaluronic acid by fibroblast.

Clinical Features

- *Age and sex distribution*—it is common in young adults with slight female predilection.
- *Site*—gingiva is the most common site followed by hard palate.
- *Appearance*—lesion is sessile, painless and nodular mass of same color of surrounding tissue (**Fig. 15-12**).
- *Surface*—it is smooth and non-ulcerated.
- *Size*—size can vary from few mm to 2 cm in diameter.

Fig. 15-12: Oral focal mucinosis showing nodular mass on gingiva which has got sessile base.

Diagnosis

- *Clinical diagnosis*—sessile painless mass on gingiva with same color may suspect this tumor.
- *Laboratory diagnosis*—biopsy shows non-encapsulated area of loose myxomatous connective tissue surrounded by collagenous connective tissue.

Management

- *Surgical excision*—it is the treatment of choice in oral focal mucinosis.

Myxofibroma

Some areas of fibroma undergo myxomatous degeneration.

Clinical Features

- *Site*—it occurs anywhere in the oral cavity, most commonly on palate, lip and gingiva.
- *Signs*—it feels softer than fibroma and is less pale.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Laboratory diagnosis*—there are regions of dense fibroblastic tissue which are interspersed with pale myxomatous appearing tissue.

Differential Diagnosis

- *Plexiform neurofibroma*—it is spongy and fluctuant.

Management

- *Complete excision*—complete excision of the lesion should be carried out.

Myxoma

Myxoma appears to be true neoplasm which consists of tissue that resembles mesenchymal tissue. Soft tissue myxoma is very rare in the oral cavity.

Clinical Features

- *Age and sex*—it can occur at any age and there is no definite sex predilection.
- *Site*—it occurs on skin of the subcutaneous tissues, genitourinary tract and gastrointestinal tract, or liver, spleen, or even in parotid gland. Intraorally, it occurs on the tongue, buccal mucosa and retromolar area.
- *Appearance*—it is present as soft tissue growth in oral cavity.
- *Nerve sheath myxoma*—it arises from perineural cells of peripheral nerves and contain prominent mucoid matrix. It may be present on tongue, buccal mucosa and retromolar area.

Diagnosis

- *Clinical diagnosis*—it is not specific.
- *Laboratory diagnosis*—biopsy shows loose textured tissue which contains delicate reticulin fibers and mucoid material, probably hyaluronic acid.

Management

- *Surgical*—it is essentially surgical and recurrence is common.

Tumors of Cartilage Tissue Origin

Chondroma

It is a benign cartilaginous tumor. In spite of the fact that mandible and maxilla are membranous bones, they sometimes contain vestigial rests of cartilage.

Types

- *Enchondroma or central*—it develops deep into the bone. It is most commonly seen.
- *Ecchondroma*—it develops on the surface.

Origin

- *Meckel's cartilage*—it is present in the mandibular arch, prior to the appearance of the bone. It usually disappears with the occurrence of ossification in the mandibular arch, but it is possible that the remnants still persist.
- *Fibrocartilage*—in some cases, secondary cartilage like fibrocartilage of mandibular symphysis may persist in the jaw bone and thus can give rise to chondroma.
- *Chondrocranium*—the maxilla develops in close association with chondrocranium. The maxillary sinus develops as an outgrowth from the lateral walls of the nasal capsule. As it grows into the maxilla, it may take remnants of the cartilage from the capsule.
- *Remnants of paraseptal cartilage*—in some cases, remnants of the paraseptal cartilage might persist within the maxilla.

Clinical Features

- *Age and sex*—it occurs in the 5th and 6th decades and males are slightly favored.
- *Site*—it usually occurs in the phalanges and metacarpals. Intraorally, maxilla is slightly favored and it occurs in the anterior region, while in mandible it occurs in premolar-molar region and at symphysis; it may be found in condyle and coronoid process.
- *Symptoms*—it is painless, slowly growing and is locally invasive. Teeth become loose and may be exfoliated.
- *Signs*—the overlying mucosa is seldom ulcerated.
- *Syndrome associated*—it is associated with *Ollier's syndrome*, in which there are multiple enchondromatosis. It is also seen in *Maffucci syndrome* in which there are soft tissue angiomas.

Radiographic features

- *Radiodensity*—irregular radiolucent areas.
- *Margins*—borders may be well defined or ragged or poorly defined.
- *Mottled or blurry appearance*—it may develop radiopacities in osteolytic areas, which produce **mottled (Fig. 15-13) or blurry appearance**.

- *Effect on surrounding structure*—jaw is sometimes expanded by the tumor or the lesion which may cause destruction of the lateral margins, so that it is uncovered by bone in this area. Resorption of involved teeth occurs.
- *Loculated type*—some of the central chondromas may be loculated but it is more likely due to surface strands of bone than due to actual partitions.
- *Ecchondroma*—it is usually situated in the mandibular notch. The coronoid process is directed forward and upward at a much less steep angle, although its length and width are normal.

Fig. 15-13: Mottled appearance seen in chondroma in mandibular posterior region (Courtesy Dr Parate).

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—mottled appearance in jaw.
- *Laboratory diagnosis*—biopsy shows hyaline cartilage with calcification or necrosis. Cartilage cells are small.

Differential Diagnosis

- *Chondrosarcoma*—pain is present in case of chondrosarcoma.
- *Osteogenic sarcoma*—typical sun ray appearance is seen.
- *Osteoblastic metastatic carcinoma*—presence of primary tumor.
- *Ossifying sub-periosteal hemangioma*—aspiration should be done to rule out hemangioma.
- *Fibrous dysplasia*—ground glass appearance and histological features.

Management

- *Surgical*—tumor should be excised along with the lining capsule. It should be covered by chip graft. Recurrence is common.

Chondroblastoma

It is also called as 'Codman's' tumor. It usually involves long bone. In some cases, it may be found in cranial bones.

Clinical Features

- *Age and sex*—it occurs in young persons, under the age of 25 years, with male predominance over the female, usually in the ratio of 2:1.
- *Site*—it occurs usually in epiphyseal region of long bones. The usual site is femur and tibia. In some cases, it can occur in condyle of mandible.
- *Symptoms*—it is slow growing, painless mass.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Laboratory diagnosis*—it consists of uniform, closely packed, polyhedral cells, with occasional foci of chondroid matrix. Multinucleated giant cells are also present.

Management

- *Surgical excision*—conservative surgical excision is carried out. Recurrence is possible after excision.

Chondromyxoid Fibroma

It is an uncommon benign tumor of cartilaginous derivation.

Clinical Features

- *Age and sex*—it occurs in young persons under the age of 25 years, with no definite sex predilection.
- *Site*—it is extremely rare in jaws, but there are some cases reported in mandible. It is more commonly seen in metaphyseal region of long bone.
- *Symptoms*—pain is the outstanding feature of this disease and sometimes, swelling can be seen.

Radiological Features

- *Margin*—margin is sclerotic and scalloped.
- *Appearance*—it is circumscribed radiolucent defect. Central radiopacity is present within the radiolucent defect.
- *Size*—size of lesion varies from 1 to 6 cm.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological features*—radiolucent defect with central radiopacity.

- *Laboratory diagnosis*—biopsy shows myxomatous and fibrous areas and it gives a chondroid appearance. Foci of calcification can be seen.

Management

- *Surgical excision*—conservative surgical excision can be done.

Tumors of Adipose Tissue Origin

Lipoma

It seldom occurs in oral cavity. It is a benign, slow growing tumor composed of mature fat cells. Lipoma appears to be common in obese patient.

Types

- *Encapsulated lipoma*—it is the commonest tumor.
- *Diffuse lipoma*—it does not possess typical features of lipoma. It is also called as 'pseudolipoma'.
- *Lipomatosis*—it has multiple lipomas. It refers to the symmetrical masses of fat, which sometimes occur around the neck in middle aged man and occurs as painful deposits of fat in women in Dercum's disease.

Clinical Features

- *Age and sex distribution*—occurs age after 40 years with peak at 50 years, male to female ratio is 1:1.
- *Common sites*—it usually occurs in upper parts of the trunk, neck (Fig. 15-14) and arms. In oral cavity, it occurs on buccal mucosa and mucobuccal fold followed by tongue, floor of mouth and lip.

Fig. 15-14: Lipoma present on skin in submental region (Courtesy Dr Chole).

- *Appearance*—it appears as a solitary lesion with sessile, pedunculated or submerged base.
- *Size*—size of lesion is approximately 1 cm in diameter.
- *Margins*—well contoured, well defined (Fig. 15-15), round to large ill defined lobulated mass.

Fig. 15-15: Well defined mass of lipoma seen on buccal mucosa (Courtesy Dr Bande).

- *Shape*—it grows as round (Fig. 15-16) or ovoid mass in oral cavity.

Fig. 15-16: Rounded swelling of lipoma seen on buccal mucosa.

- *Base*—it may be lobulated or may be broadly based or have narrow pedicle.
- *Color*—due to thinness of the overlying epithelium, yellow coloration of the fat can be seen.
- *Signs*—surface is smooth, non-tender, soft and cheesy in consistency. The epithelium is usually thin and the superficial blood vessels are readily visible over the surface. Some lesions of lipoma are deep and feel fluid in consistency on palpation; and can be mistaken as cysts.
- *Slip signs*—the edge of lipoma is soft, compressible and often slips away from the examining fingers.
- *Transillumination test*—it may be positive.

- *Lipoblastomatosis*—it is a variant of lipoma, but is not a true neoplasm. It is the continuation of the normal process of fetal fat development carried into the postnatal life. It is characterized by the occurrence in infants. Clinically as a solitary or multiple soft tissue masses, developing at various sites such as the buttocks, chest, axilla or neck.
- *Hibernoma*—it is developed as multi-vacuolated fat that is analogous to the brown fat of hibernating animals; however lesions in oral cavity are not reported.

Diagnosis

- *Clinical diagnosis*—positive slip sign, soft well defined swelling will go in favor of lipoma.
- *Laboratory diagnosis*—biopsy shows mature fat cells, collagen strands coursing through the lesion.

Management

- *Local excision*—surgical excision is done. Recurrence is uncommon.

Bone Tumors

Osteoma

It is a benign neoplasm characterized by proliferation of either compact or cancellous bone, usually in an endosteal or periosteal location.

Origin

- *Periosteal*—it arises on the surface of bone as a pedunculated mass.
- *Endosteal*—it is located in the medullary bone.

Types

- *Ivory osteoma*—it consists of compact bone, which has dense lamellae of bone.
- *Cancellous osteoma*—consisting of trabeculae of bone.
- *Combination*—it is a combination of compact and cancellous variety.

Clinical Features

Ivory osteoma

- *Age and sex distribution*—it occurs in individuals older than 40 years. It is more common in males, as compared to females.
- *Site*—it occurs exclusively on skull and facial bone. It may occur in more than one bone. Mandible is more affected on the lingual side of ramus and inferior border, below the molars.

- *Symptoms*—it is usually painless. Osteoma which arise in sinus can cause sinusitis, headache and ophthalmologic manifestation.
- *Appearance*—asymmetry is caused by bony hard swelling of jaw.
- *Osteoma of condyle*—this may cause deviation of mandible towards the unaffected side (Fig. 15-17).

Fig. 15-17: Osteoma presenting as swelling at angle of mandible (Courtesy Dr Datarkar).

- *Signs*—Mucosa is normal in color and freely movable. Mandibular lesion may be exophytic extending outwards in soft tissues. Ivory osteoma of the jaw is sometimes pedunculated.
- *Osteomatosis*—multiple osteoma may occur as a feature of Gardner's syndrome. Multiple osteoma can also occur in absence of other abnormalities. They have been reported in the mandible, frontal and maxillary sinus. Multiple osteoma rarely occur in soft tissue.

Cancellous osteoma

- *Age and sex*—it more commonly occurs in females with age same as for ivory osteoma.
- *Site*—there is predilection to occur in the alveolar process.
- *Base*—it is usually pedunculated, although it might have a broad base.
- *Surface*—the surface may be smooth or slightly irregular.

Radiographic Features

Ivory osteoma

- *Site*—there is small mass of dense bone situated below the level of the root of lower molar. It may be located within paranasal sinus.
- *Size*—the size of mass is usually few centimeters in diameter.
- *Appearance*—it appears as a uniform radiopaque mass (Fig. 15-18). There may be granular appearance in some

cases. It appears as a homogenous radiodensity without any internal structure.

- *Margins*—it has well defined borders.

Fig. 15-18: Well defined completely radiopaque lesion present due to osteoma.

Cancellous osteoma

- *Internal structure*—it shows evidence of internal trabecular structure. Due to these trabeculations, individual spaces appear to be small. There may or may not be superficial layer of cortical bone.
- *Bone structure*—bone structures, within the tumor, are continuous with that of the parent bone.

Diagnosis

- *Clinical diagnosis*—it is not possible to make clinical diagnosis.
- *Radiological diagnosis*—well defined complete radiopaque lesion will give clue to diagnosis. CT scan may be useful in some cases (**Fig. 15-19**).

Fig. 15-19: CT scan showing osteoma on right side in condylar region.

- *Laboratory diagnosis*—biopsy shows extremely dense compact bone or coarse cancellous bone.

Differential Diagnosis

- *Solid odontome*—there is absence of soft tissue capsule in cases of osteoma and is present in solid odontome.
- *Fibrous dysplasia*—fibrous dysplasia does not reveal the same homogenous density like that of osteoma. Osteomas has usually clearly defined borders.
- *Osteochondroma*—osteochondroma has a cartilaginous capsule and may be associated with irregularity on the surface of the tumor.
- *Sclerosing osteitis*—the margins of sclerosing osteitis tend to be ill defined and in cases of osteoma, margins are well defined. Usually the cause is identified in cases of sclerosing osteitis.
- *Enostosis*—there is absence of any mass on the surface of bone in enostosis.
- *Osteosarcoma*—here, there is bony enlargement with sun-ray appearance.
- *Chondrosarcoma*—same as osteosarcoma.
- *Ossifying fibroma*—bony enlargement with dense radiopaque mass.

Management

- Resection of osteoma is generally successful.

Osteoblastoma

It is also called as 'giant osteoid osteoma'. It is a benign uncommon tumor of osteoblasts, with area of osteoids and calcified tissues.

Clinical Features

- *Age and sex distribution*—male to female ratio is 2:1. Most lesions occur in 2nd and 3rd decades of life.
- *Site*—it more commonly occurs in vertebral column and sacrum. It is rare in jaws and if it occurs, found more commonly in tooth bearing areas of mandible.
- *Symptoms*—it is characterized by pain and swelling of the affected region, which may be of few weeks to a year duration. Pain is not relieved by aspirin as compared to osteoid osteoma.
- *Signs*—there is local expansion of the bone.
- *Aggressive osteoblastoma*—it is characterized by locally aggressive behavior. It is seen in older patient. Pain is present and severe.

Radiographic Features

- *Site*—it is seen in tooth bearing region and temporomandibular joint.

- **Radiodensity**—it may be entirely radiolucent or show varying degree of calcification (**Fig. 15-20**).
- **Margins**—borders may be diffuse or show some signs of cortication. Mandibular lesion may contain a radiolucent halo with outer cortical boundaries.
- **Appearance**—the tumor may show varying degree of calcification which may take a form of sunray or fine granular bone trabeculae.

Fig. 15-20: CT scan of osteoblastoma showing mixed lesion with radiopaque foci in the lesion.

Diagnosis

- **Clinical diagnosis**—bony pain which is not relieved by aspirin with swelling in jaw may suspect osteoblastoma.
- **Radiological diagnosis**—well defined lesion with patchy distribution of mineralization.
- **Laboratory diagnosis**—biopsy shows dilated capillaries, multinucleated giant cells and proliferating osteoblasts.

Differential Diagnosis

- **Osteoid osteoma**—more eccentric radiolucency with sclerotic borders. Histologically, osteoid trabeculae in osteoblastoma are larger, broader and longer, with wider trabecular space than those in osteoid osteoma. An osteoblastoma is more vascular and less painful. Size of osteoblastoma is more than 2 cm and size of osteoid osteoma is less than 2 cm.
- **Osteogenic sarcoma**—benign radiographic appearance of osteoblastoma, as compared to osteogenic sarcoma.

Management

- Curettage and conservative surgical excision. Recurrence may occur.

Osteoid Osteoma

It is a variant of osteoblastoma. It is a true neoplasm of osteoblastic derivative. It is small oval or rounded tumor-like nidus which is composed of osteoid and trabeculae of newly formed bone deposited within the substratum of highly vascularized osteogenic connective tissue tumor. It has usually intracortical lumen. It contains concentration of peripheral nerves which is not seen in other bony lesion.

Clinical Features

- **Age and sex distribution**—it occurs in males between the age of 10 and 15 years.
- **Site**—any part of the skeleton is involved, including the small bone of the hands, feet and vertebrae. The skull and jaws are rarely involved, with slight predilection for the mandible.
- **Symptoms**—the main feature of this neoplasm is severe pain, in spite of the small size of the lesion. Pain aggravates as tumor secretes prostaglandins. Pain usually occurs at night.
- **Signs**—soft tissues over the involved bone area may be swollen and tender.
- **Shape**—it is an oval or round tumor-like lesion.
- **Size**—it has a core of about 1 cm in diameter.
- **Extent**—there tends to be a marked reaction, which may extend for a considerable distance from the tumor itself.

Radiographic Features

- **Site**—in the jaws, it develops in the body of mandible.
- **Appearance**—In some cases, there is a dense area of sclerosis in the bone and it may vary from a narrow zone to a more extensive area of several centimeters.
- **Shape**—small ovoid or round radiolucent area less than 1 cm in diameter.
- **Margins**—these are well defined and surrounded by rim of sclerotic bone.
- **Target-like appearance**—the central radiolucency may exhibit some calcification, which manifests in the form of radiopaque foci on radiographs. This will produce target-like appearance.
- **Effect on surrounding structures**—In occlusal view, the overlying cortex is thickened by new bone being formed subperiosteally.

Diagnosis

- **Clinical diagnosis**—bony pain which is relieved by aspirin with swelling in jaw may suspect osteoid osteoma.
- **Radiological diagnosis**—well defined lesion with size less than 2 cm with target-like appearance will give clue to diagnosis.

- *Laboratory diagnosis*—biopsy shows highly vascularized osteogenic connective tissue. There is central nidus composed of compact osteoid tissue, varying in degree of calcification, interspersed by a vascular connective tissue.

Differential Diagnosis

- *Sclerotic osteitis*—there is presence of central radiolucency, in cases of osteoid osteoma.
- *Ossifying fibroma*—root resorption is rare in osteoid osteoma, but is frequently present in ossifying fibroma. Osteoid osteoma is located more on the inferior aspect.
- *Monostotic fibrous dysplasia*—it is common in maxilla and there is no central radiolucency.
- *Benign cementoblastoma*—the lesion is surrounded by radiolucent halo; while in case of osteoid osteoma, there is central radiolucency.
- *Periapical cemental dysplasia*—it is exclusively found in females.
- *Osteoblastoma*—it is less painful than osteoid osteoma.

Management

- *Salicylates*—severe pain may be relieved by mild obtundants such as aspirin.
- *Excision*—complete excision of tumor is carried out.

Osteochondroma

It is most likely to represent a choristoma, rather than a neoplasm. It is developmental in origin. There is intermingling of two lesions resulting in the term osteochondroma.

Clinical Features

- *Age and sex*—it occurs most often in women, between the ages of 20 and 39 years.
- *Site*—it is commonly seen in lower end of femur, upper end of tibia. It is rare in jaw and if found, it is seen in coronoid process of mandible and mandibular condyle. In some cases, tongue may be involved.
- *Symptoms*—dysphagia may be the only symptom in this patient. If there is involvement of the condyle, there is difficulty in movements of mandible. Pain is experienced, either in opening and closing the mouth or in deviating the mandible to one side.
- *Appearance*—on the tongue, it appears as a pedunculated swelling of about 1 to 2 cm in the posterior part of the dorsum of tongue, near the foramen cecum.
- *Sign*—there is facial asymmetry and lesion has got broad base.

Radiological Features

- *Appearance*—the radiolucent area in the bone tends to be spherical or oval in shape.
- *Margins*—margins of the tumor tend to be more sharply localized and corticated.
- *Internal structure*—it shows the presence of bone in the lesion, unlike chondroma which does not show any bone in the lesion. The bone within the tumor is either trabecular or as irregularly shaped amorphous mass.
- *Coronoid process*—in some cases, coronoid process is enlarged, resembling a *drumstick* appearance.
- *Effect on surrounding structures*—the malar bone may show destruction of bone on its deep and inferior surface, while superficial surface of the adjacent maxilla is indented to receive the additional size of the coronoid.

Diagnosis

- *Clinical diagnosis*—if deviation of mandible during mouth opening, facial asymmetry in the condylar lesion is present, this disease should be suspected.
- *Radiological diagnosis*—drumstick appearance of coronoid process and radiolucent lesion seen in condyle will give clue to diagnosis.
- *Laboratory diagnosis*—biopsy shows a well circumscribed lesion of mature lamellar bone, cartilage or a mixture of those tissues. Haversian canals may be present in the bone and rarely, blood forming elements may be present.

Management

- *Surgical excision*—surgical excision of the lesion should be carried out.

Torus Palatinus

It is also called as '*palatine torus*'. It is a slowly growing flat based bony protuberance or excrescence which occurs in the midline of the hard palate. It occurs in about 20% of the population.

Etiopathogenesis

- *Genetic*—it is inherited as autosomal dominant trait.
- *Functional stress*—environmental factors such as functional stress can also lead to torus palatinus.

Types

They are classified according to their morphology

- *Flat torus*—it has broad base and smooth surface. Extent of this tori is even on both side of midline of palate.
- *Spindle torus*—it has midline ridge along the palatal raphe.

- *Nodular torus*—in this, multiple protuberances with individual base are present. Groove may form in the midline.
- *Lobular torus*—it has lobulated mass with single base. It can be sessile or pedunculated.

Clinical Features

- *Age and sex*—females are affected twice more commonly than males. Development is initiated in young adults, before 30 years.
- *Site*—it occurs in the midline of the palate and may extend to involve the palatal process of the palatine bone.
- *Progress*—the growth may be slow or there may be a period of rather rapid growth which ceases altogether before the patient has advanced into adult life.
- *Size*—they are usually less than 2 cm in diameter. In some cases, lesion may progress to such an extent that it can fill whole palatal surface.
- *Signs*—it is covered with normal mucosa, which appears pale and occasionally ulcerated, when traumatized.

Radiographic Features

- *Radiodensity*—there is relatively dense radiopaque shadow.
- *Site*—if the torus has developed in the middle or anterior regions of the palate, it will be superimposed with apical area of maxillary teeth (**Fig. 15-21**). If it occurs in posterior area, it will appear on the roots of maxillary molars.
- *Margins*—borders are well defined as the surface of the torus is of compact bone.
- *Shape*—there is more or less rounded and sharply defined eminence, which stands well above the palate. Occlusal film that it includes the posterior borders of hard palate will provide good demonstration of palatal torus, which will appear oval in shape.

Fig. 15-21: Increased radiopacities seen at the apex of maxillary anterior of palatal tori.

Management

- *Surgery*—as it is benign it is usually not treated, except in some cases where patient requires a complete denture and tori is causing more undercuts and problems for fitting of complete denture. In these cases surgical removal of tori can be done.

Torus Mandibularis

It is also called as '*mandibular torus*'. It is an exostosis or outgrowth of bone found on the lingual surface of the mandible. They consist primarily of compact bone. it occurs in 8% of the population.

Causes

- *Genetic*—it occurs as an autosomal dominant trait.
- *Masticatory stress*—masticatory stress is reported as an essential factor underlying the formation. The reason behind is that torus mandibularis is seen in patient who is having bruxism.

Clinical Features

- *Age and sex distribution*—it is usually discovered in middle aged adults. There is no sex predilection.
- *Site*—it may occur singly, multiply, unilaterally, but is usually bilateral in premolar region.
- *Sign*—there is growth on the lingual surface of the mandible, above the mylohyoid line, usually opposite to the bicuspid teeth (**Fig. 15-22**). Overlying mucosa may get ulcerated in some cases.
- *Size*—their size is variable ranging from an outgrowth that is just palpable to one that contacts a torus on the opposite side.

Fig. 15-22: Torus mandibularis presented as swelling in the bicuspid region (Dr Bande).

Radiographic Features

- **Site**—radiopaque shadow superimposed over the roots of premolars and molars and occasionally, on the incisors and canine.
- **Margins**—they are sharply demarcated anteriorly, on the periapical film and less dense and less well defined as they extend posteriorly.
- **Shape**—the shadow tends to be oval with long axis in the posteroanterior direction.
- **Appearance**—on occlusal radiograph, tori appear as radiopaque, homogenous, knobby protuberances from the lingual surface of mandible. Borders are not sharp between it and bone, but it is continuous suggesting that it is a part of the bone rather than a growth.

Management

- **Surgery**—removal may be necessary, if a mandibular denture is planned.

Exostosis

It is also called as '*hyperostoses*'. They are small regions of osseous hyperplasia of cortical bone and occasionally, cancellous bone, on the surface of the alveolar process. They are less common than mandibular and palatal tori.

Clinical Features

- **Age and sex distribution**—it is more commonly seen in adults as compared young.
- **Site**—it may develop on the palatal surface of maxillary alveolar process, at the border between the attached gingiva and vestibular mucosa, in canine or molar area.
- **Size**—they seldom attain large size and may be solitary or multiple.
- **Shape**—their shape may be nodular, pedunculated or flat protuberance on the surface of bone.
- **Consistency**—they are bony hard on palpation.
- **Buccal exostoses**—it usually occurs as bilateral row of bony hard nodule on buccal aspect of an alveolar ridge. Ulceration of overlying mucosa may occur if trauma occurs.
- **Palatal exostoses (palatal tubercle)**—it is also bilateral and seen in maxillary tuberosity area.
- **Solitary exostoses**—it occurs as reaction of local irritation. Mostly occur below the free gingival graft (**Fig. 15-23**).
- **Reactive subpontine exostosis (subpontic osseous proliferation, subpontic osseous hyperplasia)**—it occurs from alveolar crestal bone beneath the pontic of posterior bridge.

Radiographic Feature

- **Radiodensity**—the internal aspect of an exostosis usually is homogenous and radiopaque.

Fig. 15-23: Solitary exostosis seen on buccal aspect of maxillary molar (Courtesy Dr Abhishek Soni).

- **Appearance**—they appear as circumscribed, smoothly contoured, rounded radiopaque masses.
- **Margins**—they are well defined, but some lesions may poorly blend, radiographically into the surrounding bone.

Management

- **Surgical**—surgical removal is required if exostosis is exposed to frequent trauma and if you want to place prosthesis in that area. Reactive subpontine exostoses need to be removed as they interfere with oral hygiene.

Enostosis

It is also called as '*dense bone island*'. They are internal counterparts of exostosis. They are localized growth of compact bone that extends from the inner surface of cortical bone into the cancellous bone. It is also called as '*whorl*'. A rare condition in which there are thousands of dense islands of bone scattered through the skeleton is known as '*osteopoikile*' or '*osteopoikilosis*'.

Clinical Features

- **Age**—it is more commonly seen in 2nd and 3rd decade.
- **Site**—it is more common in mandible than maxilla and commonly found in premolar molar area.
- **Symptoms**—it is asymptomatic.

Radiographic Features

- **Margins**—single isolated radiopacities that may be either well defined (**Fig. 15-24**) or diffuse, so that the trabeculae blend with trabecular pattern of adjacent normal bone of jaw.
- **Size**—it is more or less rounded, with size varying from a few millimeters up to a centimeter or more.

Fig. 15-24: Single isolated radiopacity seen at the apex of first molar suggestive of enostosis (Courtesy Dr Parate).

- **Teeth**—in rare cases there may be external root resorption of the teeth when it is located periapical to the tooth.

Diagnosis

- **Clinical diagnosis**—not possible to make clinical diagnosis.
- **Radiological diagnosis**—rounded opacity with lack of expansion will give clue to diagnosis.

Differential Diagnosis

- **Periapical idiopathic osteosclerosis**—difficult to distinguish, but these periapical lesions may be associated with periodontal ligament widening, which is absent in case of enostosis.
- **Periapical cemental dysplasia**—radiolucent margins.
- **Hypercementosis**—associated with roots of teeth.
- **Cementoblastoma**—it is also associated with roots of teeth.
- **Osteosarcoma**—radiolucent component is present.
- **Metastatic osteoblastic carcinoma**—radiolucent component is present.
- **Chondrosarcoma**—radiolucent component is present.

Management

- **No treatment**—most cases are unrecognized and are not clinically important.

Tumors of Vascular Tissue Origin

Hemangioma

It is also called as '*vascular nevus*'. It is a benign tumor which occurs most commonly in vertebrae and skull. It is characterized by proliferation of blood vessels. It is often congenital in origin. It is composed of seemingly disorganized vessels that are filled with blood and is connected to the main vascular system.

Types

- **Central**—it occurs in the bone.
- **Capillary hemangioma**—it is a mass of intercommunicating capillary vessels of more or less normal size and structure.
- Strawberry angioma.
- Port-wine stain.
- Salmon's patch.
- **Cavernous hemangioma**—it consists of dilated blood containing spaces, lined by endothelium.
- **Arterial or plexiform hemangioma**—it arises from arteries.

Clinical Features

Central

- **Age and sex distribution**—most of cases are found at birth or arise at early age. Female to male ratio is 2:1.
- **Origin**—the lesion can originate either from the periosteum and resorbs the underlying bone or it occurs within the bone as an anomaly of blood vessels in the marrow spaces.
- **Site**—mandible to maxilla ratio is 2:1. 50% cases are found in mandible, mostly in the body and ramus area.
- **Symptoms**—pain is present in many cases of central hemangioma. The nature of the pain is throbbing. Patient also complaint of swelling in the jaw (**Fig. 15-25**). In some cases, there is paresthesia of skin supplied by mental nerve.

Fig. 15-25: Central hemangioma presented as swelling seen in mandibular posterior region which is red in color (Courtesy Dr Bhaskar).

- **Signs**—swelling is non-tender, compressible and in some cases bony hard in consistency (**Fig. 15-26**). On auscultation, it is pulsatile and bruit may be detected. On probing, there is presence of bleeding from gingiva around the neck of affected teeth. Aspiration of the lesion produces blood.

Fig. 15-26: Central hemangioma presented as hard swelling in the palate.

- *Pumping tooth syndrome*—it demonstrates pumping action, i.e. if the tooth is depressed into the socket, it will rebound into its original position within few minutes.
- *Effect on teeth*—teeth in affected area may be loosened and may migrate.
- *Kasabach-Merritt syndrome*—it is associated with extensive hemangioma in infants. There is also thrombocytopenia and hemorrhage due to platelet trapping within the tumor.

Cavernous

- *Age and sex*—it is common in 1st and 3rd decades and female to male ratio is 2:1. It may fluctuate in size in pregnancy and menarche. The oral or pharyngeal hemangiomas are diagnosed at an older age, than the lesions from other sites.
- *Site*—the most common site of occurrence are the lips, tongue, buccal mucosa and palate.
- *Appearance*—it appears as a flat or raised lesion of mucosa (**Fig. 15-27**).
- *Color*—it is usually bluish in color.
- *Size*—size of swelling vary, and may become larger on physical activity or standing. Size of the swelling reduces in size once the patient is flat on the examining table. Sometimes they may increase in size to such an extent that it can bury the teeth and cause serious deformity and disfigurement.
- *Signs*—Swelling is deep red or bluish red in color and seldom is well circumscribed. In some cases, the texture of mucosa may be more or less unchanged, showing an increased vascularity on the surface; but in some cases, appearance in pebbly.
- *On palpation*—the mucosal hemangioma is typically a soft, moderately well circumscribed lesion. The large lesions are warm and may even be pulsatile if associated with large vessels. The more superficial ones are often lobulated and will blanch under finger pressure. Deeper lesions tend to be dome-shaped with normal or blue surface coloration, they seldom blanch.

Fig. 15-27: Cavernous hemangioma of lip presenting as raised lesion. It is deep red in color.

- *Bleeding upon trauma*—the tumor more often is traumatized and bleeds profusely. It also undergoes ulceration with secondary infection.
- *Base*—some lesions are pedunculated and globular and some are broad based and flat or slightly raised.
- *Compressibility test*—this test is positive. After giving continued pressure and squeezing, blood will drive out of the lesion and the swelling crumbles. As soon as the pressure removed, the swelling reappears with refilling.

Fig. 15-28: Congenital hemangioma presented on tongue which is bluish in color.

- *Tongue*—in cases of hemangioma affecting the tongue, there may be loss of mobility of the tongue. Color of swelling is usually bluish (**Fig. 15-28**). It may affect a part of tongue or the entire tongue.

Capillary Hemangioma

Strawberry angioma

- *Age*—typical history of red mark is noticed after 1-3 weeks of birth. After 1st birthday, it regresses in size and involution is completed by 7 to 8 years.

- *Site*—subcutaneous tissues as well as skin are often involved. In some cases, it can be seen in the floor of mouth.
- *Strawberry appearance*—red mark increases in size for a few months, till it takes a typical strawberry or raspberry-like swelling (**Fig. 15-29**).

Fig. 15-29: Strawberry hemangioma presented as typical strawberry type lesion in the floor of mouth.

- *Color and base*—it is dark red in color. It slightly protrudes from the skin surface as a sessile hemisphere.
- *Compressibility test*—swelling is compressible.
- *Surface*—it is irregular and there may be small areas of ulceration with scabs (**Fig. 15-30**).

Fig. 15-30: Hemangioma of lip showing some areas of ulceration with scabbing.

Port-wine stain

- *Age*—it generally starts at birth and darkens as the child grows, but it does not really grow.
- *Site*—it is common on the face (**Fig. 15-31**) and at the shoulders, neck and buttock.
- *Appearance*—reddish macular hemangiomas are called as port-wine stain. The port wine stain is generally smooth, but could be slightly raised (**Fig. 15-32**).
- *Size*—it is seldom more than 5 mm in diameter.
- *Color*—it is deep purple-red in color, which may become paler later. Color blanches readily on pressure.

Salmon patch

- *Age*—it is present since birth and usually disappears before the first birthday.

Fig. 15-31: Port-wine stain presented as red macular lesion.

Fig. 15-32: Port-wine stain in the distribution of maxillary nerve presented on the face (Courtesy Dr Parate).

- *Site*—it is seen over the forehead, occiput or anywhere in the midline of the body.

Arterial or Plexiform Hemangioma

It is a type of congenital arteriovenous fistula. There is a pulsatile swelling of the arteries, veins become tortuous and thick walled; pulsatile feeling like a bag of pulsating earthworms, is elicited.

Radiographic Features

- *Site*—it is more commonly found in mandible. In mandible they are often located within the inferior alveolar canal. It can also occur in the body and ramus of the mandible.

- *Soft tissue hemangioma*—in some cases if radiograph of patient with hemangioma taken with reduced exposure, the shadow of the lesion may be seen on the radiograph (Fig. 15-33).

Fig. 15-33: Hemangioma of lip presented as increased radiopacity seen on the lower lip (Courtesy Dr Tapasya).

- *Margins*—it is well defined and corticated and in some cases, it may be ill defined.
- *Shape*—the total lesion tends to assume a rounded shape (Fig. 15-34). The bone may show fusiform enlargement at the site of the lesion.

Fig. 15-34: Central hemangioma presenting as rounded lesion in the mandibular posterior region (Courtesy Dr Bhaskar Patle).

- *Soap bubble or honeycomb appearance*—a moderately well defined zone of radiolucency is present within which the trabecular spaces get enlarged and the trabeculae themselves become coarse and thick. The lesion, therefore, presents typically a multicystic, soap bubble or honeycomb appearance (Fig. 15-35).

- *Sunray or sunburst appearance*—the large lesion may cause cortical expansion with radiating spicules at the expanding periphery, occasionally producing the sunray or sunburst appearance.

Fig. 15-35: Honeycomb appearance of hemangioma seen in mandibular posterior region.

- *Spokes of wheels appearance*—a structure of the bone is changed in the affected area so that the trabeculae are arranged in a manner which has a rough resemblance to the 'spokes of wheels'.
- *Phleboliths*—small area of calcifications or concretions occasionally within the surrounding soft tissues.
- *Effect on adjacent structures*—roots of teeth adjacent to the lesion are frequently resorbed. Inferior alveolar canal can be enlarged along its entire length and the shape may be changed to a serpiginous pattern. In some cases, the mandibular and mental foramen may be enlarged.
- *Diffuse type of hemangioma*—in it, there is bone destruction giving the appearance of clusters of cavities with ill defined or better defined margins, separated from other of the spaces by normal or rarefied bone.
- *Ultrasound*—ultrasound heterogeneous hypoechoic lesions in which calcified phleboliths are identified, are evident.
- *Computed tomography*—computed tomography shows similar appearance with enhanced quality.
- *CT angiography*—this will determine the extent of blood supply and drainage of the lesion.

Differential Diagnosis (Radiological)

- *Central giant cell granuloma*—central giant cell granuloma crosses the midline, while in hemangioma it does not cross the midline.
- *Giant cell lesions of hyperparathyroidism*—biochemical investigations should be done to rule out hyperparathyroidism.

- *Aneurysmal bone cyst*—hemangioma will show profuse hemorrhage, if aspirated.
- *Ameloblastic fibroma*—in hemangioma, honeycomb pattern and local gingival bleeding with pumping action of tooth are seen.
- *Odontogenic myxoma*—tennis racket pattern is seen in myxoma.
- *Ameloblastoma*—it usually occurs in elder age group.
- *Metastatic tumor*—history of primary tumor is present.
- *Cherubism*—it is usually bilateral and child has a typical facial appearance.
- *Traumatic bone cyst*—it is a well defined entity with better defined borders.
- *Odontogenic keratocyst*—same as traumatic bone cyst.

Management

It usually regresses by itself during adolescent period.

- *Sclerosing technique*—intralesional injections of sclerosing chemicals, such as 1 ml of 5% sodium morrhuate are effective. These agents will produce localized inflammatory reaction with resultant thrombosis, subsequent fibrosis of the endothelial spaces and regression of the lesion. After first injection second injection should be repeated after two weeks. Another agent which is used is 95% ethanol.
- *Surgery*—en bloc resection with ligation of external carotid artery. Sometimes, rash surgical excision of such central lesion of bone results in severe loss of blood, which occasionally leads to exsanguinations of the patient to the point of death. Laser surgery, cryosurgery by dry ice can also be effective.
- *Other injections*—injection of boiling water or hypertonic saline may also be given.
- *Radiation therapy* in the form of external radiation or radium can be used to successfully sclerose the lesion. But risk of inducing neoplastic changes later in life is very high and its use is contraindicated particularly in children.
- *Corticosteroids*—intralesional injections of corticosteroid can be given. This may reduce the size of tumor.
- *Flash lamp pulsed dye laser*—this is useful in case of port wine stain.
- *Embolization*—introduction of inert material into the lesion by vascular route can cause embolization and subsequent regression of the lesion.

Sturge-Weber Syndrome

It is also called as 'encephalotrigeminal angiomatosis'. It is congenital disorder belongs to grouped anomalies collectively known as phakomatoses (mother spot disease).

Classification

1st

- *Complete trisymptomatic*—in this, all three organ systems (eye, skin and CNS) are involved.
- *Incomplete bisymptomatic*—in this, involvement is either oculocutaneous or neurocutaneous.
- *Incomplete monosymptomatic*—in this, there is only neural or cutaneous involvement.

2nd—the Roach scale classification

- *Type I*—both facial and leptomeningeal angioma with glaucoma.
- *Type II*—facial angioma alone without CNS involvement. Some cases having glaucoma.
- *Type III*—isolated leptomeningeal angioma without glaucoma.

Etiology

- *Dysplasia of embryonal vascular system (Royle)*—this will result in hemangiomatosis. It occurs in sixth week of intrauterine life.
- *Developmental insult (Del)*—Sturge-Weber syndrome affects the precursor of tissue which originated in promesencephalic and mesencephalic neural crest. These developmental insults give rise to vascular malformation.
- *Aberrant migration (Crinzi)*—it may arise from aberrant migration of mesodermal and ectodermal elements in the brain and meninges in the fetal growth.

Clinical Features

- *Port-wine stain or nevus flammeus*—it is present at birth. It presents at the distribution of trigeminal nerve. The color varies from light pink to deep purple due to overabundance of capillaries beneath the surface of the involved skin (**Fig. 15-36**).

Fig. 15-36: Port-wine stain seen on left side of face in the patient with Sturge-Weber syndrome (Courtesy Dr Amit Parate).

- **Neurological features**—there is angiomas (excessive blood vessels growth) present at the birth. Patient is present with seizures (twitching of small part of body). Maximum patients of Sturge-Weber syndrome are associated with epilepsy. Prolonged seizures cause neurological injury. In some cases, patient may feel weakness on side opposite to port-wine stain. Headache can also occur.
- **Eyes**—glaucoma (increased pressure within the eye) may be present. Glaucoma occurs due to mechanical obstruction of angle of eyes. If glaucoma is left untreated, it may result in decreased vision and blindness. In some cases, enlargement of the coating of the eye (Buphthalmos) may occur.
- **Oral manifestation**—intraorally it involves oral mucosa. There is presence of vascular hyperplasia of purple color (**Fig. 15-37**). Gingival enlargement can also occur due to vascular hyperplasia.

Fig. 15-37: Intraoral purplish discoloration of oral mucosa on left side in the palate is seen (Courtesy Dr Amit Parate).

Radiological Features

- **Conventional radiography**—it may show classical 'tramlines' or tram-track' or 'trolley-track' calcification in the skull.
- **Computed tomography**—it may show calcification (**Fig. 15-38**). It can also demonstrate brain atrophy, ipsilateral choroids plexus enlargement and abnormal draining veins.
- **Angiography**—it demonstrates lack of superficial cortical veins, nonfilling of dural sinues and abnormal tortus vessels.
- **Other modalities**—other imaging modalities like MRI, SPECT, PET can also be useful.

Management

- **Cosmetic correction**—as port-wine stain is unsightly, it should be treated for cosmetic correction. The lesion can be covered by camouflage make up by dermatologist.

Fig. 15-38: Intracranial calcification seen in the brain (arrow) on the computed tomography.

- **LASER**—LASER treatment should be done to lighten and to remove port-wine stain. LASER treatment should start when the lesion is small.
- **Anticonvulsant drug**—it should be given to control seizures.
- **Anti-glaucoma medication**—topical anti-glaucoma therapy for extended period of time is helpful.
- **Dental management**—due to Sturge-Weber syndrome, hemorrhage can occur. So in dental office it should be managed carefully.

Lymphangioma

It is a benign hamartomatous proliferation of lymphatic vascular tissue. It is a hamartoma, rather than a neoplasm. In it, abnormal vessels are filled with clear protein rich fluid containing lymph rather than blood.

Types

- **Superficial or lymphangioma simplex (capillary lymphangioma)**—it presents a circumscribed lesion, which appears as small blisters and slightly elevated skin patches. It involves capillary size vessels.
- **Cavernous lymphangioma**—it is composed of larger dilated lymphatic vessels.
- **Cystic or deep lymphangioma**—they are large, cystic, and translucent and may be seen in the neck, mediastinum or axilla. These are called as *cystic hygroma*.

Clinical Features

- **Age**—they may present at birth with majority becoming clinically evident early in life, but with a small number not being manifested for a number of years.

- **Incidence**—it may occur alone or in association with hemangioma or other anomalous blood vessels.
- **Site**—it occurs in dorsal and lateral borders of tongue, lips, gingiva and buccal mucosa. On face it can involve eyes (**Fig. 15-39**).
- **Symptoms**—usually the disfigurement is noticed by the child parents. Occasionally, the vesicles may be rubbed with clothes, get infected and become painful.
- **Appearance**—they are soft masses that dissect along the tissue planes and turn out to be more extensive than anticipated.
- **Surface**—the surface of the lesion may be smooth or nodular.
- **Color**—color ranging from normal mucosal pink to bluish and may be quite translucent.

Fig. 15-39: Lymphangioma affecting left eye of the patient (Courtesy Dr Bhaskar Patle).

- **Signs**—they are liable to trauma. Due to this, lesions are subjected to periodic attacks of inflammation which cause the swelling to become larger and tender for the time being.
- **Aspiration**—aspiration yields lymph that is high in lipid.
- **Tongue**—if the tongue is affected, enlargement may occur and the term 'macroglossia' is applied. On the tongue, it is characterized by irregular nodularity of the surface of the tongue with gray and pink, grape-like projection. They are often elevated and nodular in appearance and may have the same color as the surrounding mucosa.
- **Lip**—lip involvement and its deformity is called as macrocheilia.

Radiological Features

- **CT feature**—this will show destructive lesion. Contrast CT will show a mass in the lesion (**Fig. 15-40**)

Fig. 15-40: CT scan of lymphangioma of eye showing destructive lesion of left eye (Courtesy Dr Bhaskar Patle).

Diagnosis

- **Clinical features**—irregular nodular lesion of tongue can give clue to diagnose lymphangioma.
- **Laboratory diagnosis**—capillary types are composed of proliferation of thin walled endothelium-lined channels, primarily devoid of erythrocytes. Cavernous type is characterized by presence of dilated sinusoidal endothelium-lined vascular channels, devoid of erythrocytes.

Management

- **Surgical removal**—it is done to remove bulk of the lesion. Partial or complete spontaneous involution is occasionally noted.
- **Sclerosing agent therapy**—as such it does not respond to sclerosing agents. But some success has been reported by using OK-432 a lyophilized incubation mixture of low virulent strain of *Streptococcus pyogenes* with penicillin G potassium which has lost streptolysin S producing ability.

Arteriovenous Fistula

It is also called as 'arteriovenous shunt' or 'arteriovenous malformation'. It is a direct communication between an artery and vein that bypasses the intervening capillary bed. It may be congenital or acquired.

Classification

- **Cirroid aneurysm**—it is a tortuous mass of small arteries and veins linking a larger artery and vein.

- *Varicose aneurysm*—it consists of endothelium-lined sac connecting an artery and a vein.
- *Aneurysmal varix*—it is a direct connection between artery and vein.

Clinical Features

- *Sites*—head and neck are the most common site. It can occur in alveolar ridge, palate and soft tissues.
- *Symptoms*—there is mass of extraosseous soft tissue swelling.
- *Color*—it is having purplish discoloration.
- *Signs*—bone may be expanded. Pulse may be detected on auscultation and aspiration produces blood.
- *Post-extraction bleeding*—it will result in severe bleeding after the extraction of tooth. In some cases it can be life threatening.

Radiographic Features

- *Site*—it develops in the ramus and retromolar areas of the mandible and may also involve the mandibular canal.
- *Radiodensity*—it causes a resorptive radiolucent lesion.
- *Margins*—they are well defined and corticated.
- *Appearance*—it is multilocular. Walls of shunt may contain apparent calcified material.
- *Angiography*—it is seen as abnormal collection of vessels located in the suspected area, with many vessels feeding and draining the lesion.

Diagnosis

- *Clinical diagnosis*—a lesion with a thrill or bruit, or with an obviously warmer surface, is most likely a special vascular malformation, called arteriovenous malformation
- *Radiological diagnosis*—irregular alveolar canal will give clue to the diagnosis. Angiography (**Fig. 15-41**) and contrast study CT scanning will be helpful in conforming the diagnosis.

Differential Diagnosis

- *Hemangioma*—soft tissue hemangioma does not involve the bone.
- *Ameloblastoma*—aspiration of arteriovenous shunt will produce blood which is not seen in tumor.
- *Radicular cyst*—it is associated with a non-vital tooth.
- *Dentigerous cyst*—it surrounds the crown of the tooth.

Management

- *Surgical excision*—it should be treated by surgical excision.

Fig. 15-41: Angiography showing abnormal collection of vessels (Courtesy Dr Datarkar).

Glomus Tumor

It is also called as 'glomangioma'. It is a rare neoplasm derived from glomus cells. They are thought to be closely related to hemangiopericytoma. The glomus is arteriovenous anastomosis that controls the blood supply and temperature of the skin and certain deeper tissues. These functions appear to be mediated in some way by the rich nerve supply and by certain epithelioid cells that ensheath the arteriole of the glomus. The epithelial cells are thought to be comparable to pericytes.

Clinical Features

- *Age*—the tumor usually occurs in the 5th decade.
- *Site*—the tumor probably arises from these specialized glomus cells and occurs most frequently under the nails and on the body surface especially in head and neck area. In the oral cavity the lesion is usually located on the dorsum of the tongue, lip, palate, buccal mucosa and tongue.
- *Size*—they are small lesions, rarely exceeding 1 cm in diameter.
- *Symptoms*—they often give rise to attacks of very severe pain and are exquisitely tender. Pain is stabbing in nature.
- *Color*—the color varies from deep red to purple or blue.

Diagnosis

- *Clinical diagnosis*—severe and stabbing pain with deep red color lesion will give clue to the diagnosis

- *Laboratory diagnosis*—biopsy shows glomus cells which arranged around the blood vessels in a manner suggesting hemangiopericytoma or the blood vessels may be so prominent as to resemble cavernous hemangioma.

Management

- *Surgical excision*—it is a benign tumor and removal of this surgically effects the cure.

Hemangiopericytoma

It is characterized by the proliferation of capillaries surrounded by mass of round or spindle shaped cells which are called as pericytes. It resembles to Glomus tumor but lack its organoid pattern, encapsulation and clinical manifestation of pain.

Clinical Features

- *Age and sex*—there is no sex predilection with age ranging from birth to old age.
- *Site*—it can occur at any site in the oral cavity.
- *Symptoms*—it is usually painless.
- *Appearance*—the lesions are firm, apparently circumscribed and often nodular. It may or may not exhibit redness indicative of vascular nature.
- *Progress*—majority of tumors grow rapidly and are therefore of short duration.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Radiological diagnosis*—biopsy shows proliferation of occult capillaries. Each vessel in turn is surrounded by a connective tissue sheath, outside of which are found mass of tumor cells. The tumor cells may appear large or small, round or spindle shaped and show tendency for concentric layering about the capillaries.

Management

- *Surgical excision*—local excision of the tumors is treatment of choice.

Nasopharyngeal Angiofibroma

It is also called as *juvenile nasopharyngeal angiofibroma* as its presence in younger age group. Nasopharyngeal angiofibroma is an uncommon, highly vascular, non-encapsulated polypoid mass that is histologically benign but locally aggressive. Hormonal influence is also present in this tumor.

Clinical Features

- *Age and sex*—it is more common in younger age group within the range of 10 to 18 years. It is exclusively found in males.
- *Site*—more commonly affected sphenoid sinus followed by maxillary and ethmoid sinuses.
- *Symptoms*—nasal obstruction, epistaxis, facial deformity (**Fig. 15-42**), proptosis, nasal voice, sinusitis, nasal discharge, serous otitis media, headache and anosmia.
- *Signs*—it is slow growing angiofibroma and growth is asymmetric.

Fig. 15-42: Facial deformity seen in angiofibroma (Courtesy Dr Ashok L).

Radiographic Features

- *Plain radiography features*—there is soft tissue nasopharyngeal mass. There is also widening of the pterygopalatine fossa with anterior bowing of the ipsilateral posterior antral wall. A polypoid nasal mass may cloud the ipsilateral ethmoid and maxillary sinuses.
- *Contrast-enhanced CT*—enhancing mass with appearance same as plain film radiography. Intraorbital and intracranial extension are much better visualized.
- *MRI*—it shows intermediate signal intensity on T₁ weighted and T₂ weighted sequences.

Diagnosis

- *Clinical diagnosis*—features of nasal obstruction can give some clue to this diagnosis.
- *Radiological features*—on CT, enhancing mass will present with intraorbital and intracranial extension.
- *Laboratory diagnosis*—biopsy shows dense fibrous connective tissue which contain numerous dilated thin walled blood vessels of variable size.

Management

- *Surgical excision*—surgical excision is the treatment of choice depending upon extent of lesion. Preoperative embolization will help to prevent blood clot.
- *Radiotherapy*—it is advised for recurrent lesion.

Olfactory Neuroblastoma

It is also called as '*esthesioneuroblastoma*'. It is a neural crest derived neoplasm, arising from the olfactory mucosa in the superior nasal fossa.

Clinical Features

- *Age*—it has got bimodal age distribution with first incidence in 2nd decade and 2nd incidence in 6th decade.
- *Symptoms*—the most common symptoms are nasal obstruction, epistaxis and pain.
- *Appearance*—it appears as solitary mass, sessile or pedunculated, which bleeds profusely.

Kadish Staging System

- Stage A—confined to nasal cavity.
- Stage B—nasal cavity + one or more paranasal sinuses.
- Stage C—extending beyond nasal cavity and paranasal sinuses.

Radiological Features

- *CT*—it appears as homogenous, enhancing mass that primary remodel the bone. It commonly extends into ethmoid and maxillary sinus and rarely into sphenoid sinus. Gross calcifications occur within the tumor mass.
- *MRI*—On MRI, there will be intermediate signal intensity and high T₂ weighted signal intensity are found.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—on computed tomography homogenous mass in sinus may suspect this tumor.
- *Laboratory diagnosis*—biopsy shows small, round to ovoid basophilic cells which are arranged in sheets and lobules.

Management

- *Surgical excision*—it is the treatment of choice. This surgical excision is also combined with adjunct radiation therapy.

Tumors of Neural Tissue Origin

Neurofibroma or Neurofibromatosis

Many authors described the neurofibroma and neurofibromatosis as different entity. The difference between neurofibroma and neurofibromatosis is that neurofibroma occurs as solitary lesion without café au lait spot and neurofibromatosis occurs as multiple lesions with café au lait spot. Neurofibromatosis is called as '*Von Recklinghausen's disease of skin*' or '*fibroma Molluscum*'. It is inherited as a simple autosomal dominant trait with variable penetrance.

Origin

- *Schwann cells and axon*—it arises from the connective tissue sheath of Schwann cells and axons.
- *Sites of origin*—there are three sites of origin: within the inferior dental canal, in the substance of the bone and beneath the periosteum.

Clinical Features

- *Age and sex distribution*—it occurs at any age but is found more in younger group with no sex predilection.
- *Site*—most commonly affected sites are trunk, face and extremities.
- *Appearance*—it may appear as numerous sessile (**Fig. 15-44**) or pedunculated, elevated smooth surfaced nodules of variable size, which are scattered over the skin surface. In some cases, loose overgrowth of thickened, pigmented skin may hang in folds (**Fig. 15-43**).
- *Elephantiasis neuromatosa*—in other forms, there are deeper, more diffuse lesions which are often of greater proportion than superficial nodules and are sometimes referred to as '*elephantiasis neuromatosa*'.

Fig. 15-43: Overgrowth of thickened pigmented skin seen on face.

Fig. 15-44: Numerous sessile nodules seen on patient body suggestive of neurofibroma (Courtesy Dr Milind Chandurkar).

- *Bags of worms*—neurofibromatosis lesion may feel like bags of worms which is pathognomonic sign.
- *Café au lait spots*—in addition majority of the patients exhibit asymmetric areas of cutaneous pigmentation, often described as “café au lait” spots. The spots are smooth edge, yellowish tan to dark brown macules. They vary in diameter from 1 to 2 mm.
- *Crowe’s signs*—axillary freckling (brown spot on skin) is known as Crowe’s sign.
- *Lisch nodules*—it is translucent brown pigmentation on the iris.
- *Complication*—it can develop into malignant peripheral nerve sheath tumor (Neurofibrosarcoma).

Oral Manifestations

- *Common sites*—it may occur in mandibular canal, buccal mucosa, and alveolar ridge and below the periosteum.
- *Central lesion*—the central lesion may have multiple lesions, occurring in both jaws simultaneously, expanding and filling the maxillary sinus. Solitary central lesion may infrequently be associated with brown spots on skin.
- *Symptoms*—it may produce pain or paresthesia, if associated with mandibular nerve.
- *Appearance*—there are discrete, non-ulcerated nodules, which tend to be of the same color as the normal mucosa (**Fig. 15-45**).
- *Signs*—it may expand and perforate the cortex, producing a swelling that is either hard or firm on palpation.

- *Tongue*—macroglossia may be due to diffuse involvement of the tongue.

Fig. 15-45: Discrete non-ulcerated nodules seen in oral cavity due to neurofibromatosis.

Radiographic Features

- *Extraperiosteal neurofibroma*
 - *Appearance*—there is an area of bone destruction which presents a radiolucent shadow of varying density, depending on the amount of bone that has been replaced by tumor.
 - *Size*—the size of the lesion is variable from less than one centimeter up to a very large lesion.
 - *Margins*—margins of radiolucency are well defined, curved and may be hyperostotic.
- *Subperiosteal neurofibroma*—in some cases the periosteum lays down a layer of bone on the superficial aspect of the tumor. Tumor that causes relatively little indentation of the surface of the bone appears as radiolucent areas, the darkness depending on the depth of bone loss; deeper lesion causing greater darkness in the radiograph than the superficial ones. There is tendency for the shadow to be more or less circular and there may be well defined margins, with or without a bony cortex.
- *Neurofibroma of inferior dental nerve*—it shows fusiform or more or less circular enlargement of mandibular canal. In some cases there may be an elongated lesion with an undulating border.

Diagnosis

- *Clinical diagnosis*—pigmented swelling with café au lait spots.
- *Radiological features*—radiolucent lesion with corticated border (**Fig. 15-46**).
- *Laboratory diagnosis*—it is composed of proliferation of delicate spindle cells with thin wavy nuclei intermingled with neurites in an irregular pattern as well as delicate intertwining connective tissue fibrils.

Fig. 15-46: CT scan of neurofibroma showing circular radiolucency with corticated border.

Differential Diagnosis

- *Vascular lesion*—changes in the canal from neural lesion are more localized and have a fusiform enlargement, while the vascular lesion enlarges the whole canal and alters its path.

Management

- *Surgical excision*—solitary lesion may be surgically excised.
- *Extensive lesion*—in this carbon dioxide laser and dermabrasion have been used successfully.
- *Prognosis*—it has got high potential for malignant change.

Schwannoma

It is also called as 'neurilemmoma', 'perineural fibroblastoma', 'neurinoma' and 'lemmoma'. But nowadays all above terms are not used and Schwannoma is the only term used. It is of neuroectodermal origin, arising from Schwann cells that makes the inner layer covering the peripheral nerves.

Clinical Features

- *Age and sex*—occurs at any age, from very young to very old, with equal frequency in both the sexes.
- *Site*—the tumor usually occurs in the subcutaneous tissue, but internal organs such as stomach may be affected. Intraorally, mandible and tongue is the most commonly affected site for central lesion. Other sites which can be involved in these tumors are palate, floor of mouth and buccal mucosa.
- *Progress*—it is a slow growing lesion and is usually of long duration at the time of presentation.

- *Symptoms*—usual complaint is lump in jaw, in case of central tumor and single circumscribed nodule, in case of soft tissue lesions. Paresthesia may be associated, which occurs anterior to the tumor. Pain is localized to the tumor site.
- *Extent*—usually occurs singly and jaw expansion may lead to perforation.
- *Consistency*—the mass is firm on palpation.
- *Aspiration*—it is non-productive to aspiration.

Fig. 15-47: Oval radiolucent area of bone destruction with hyperostotic border in case of neurilemmoma (Courtesy Dr Ashok L).

Radiographic Features

- *Site*—the radiolucent area is usually located within the expanded inferior alveolar nerve, posterior to the mental foramen.
- *Shape*—round to oval radiolucent area of bone destruction (Fig. 15-47). There may be crescent shaped cystic radiolucency.
- *Margins*—margins of the lesions are well defined and hyperostotic.
- *Effect on surrounding structures*—it may cause root resorption of adjacent teeth (Fig. 15-48). If the tumor protrudes from the mental foramina, erosive lesion of the surface of jaw bone occurs. The tumor may expand the inferior alveolar canal, mental foramen, mandibular foramen and mandible while maintaining the cortical boundaries.

Fig. 15-48: Root resorption associated with neurilemmoma (Courtesy Dr K Patil).

Diagnosis

- *Clinical diagnosis*—paresthesia with lump in the mandibular posterior region will suspect neurilemmoma.
- *Radiological features*—oval radiolucent lesion with corticated border.
- *Laboratory diagnosis*—biopsy shows two types of tissues: Antoni type A and Antoni type B.

Differential Diagnosis

- *Cysts*—in neurilemmoma there is an expansion of the inferior alveolar nerve canal.
- *Ameloblastoma*—it usually occurs above the canal.
- *Vascular lesion*—the expansion of the canal caused by neural neoplasm is more concentric, creating a fusiform shape; whereas vascular lesion increases the girth of the canal down the entire length and often alters the shape into a serpiginous form.

Management

- *Surgical excision*—it is the treatment of choice.

Neuroma

It is also called as 'amputation neuroma' or 'traumatic neuroma'. It is not a true neoplasm, but an exuberant attempt at repair of a damaged nerve trunk.

Etiopathogenesis

- *Causes*—nerve damage may result from fracture, dissection, removal of cyst, nerve avulsion for neuralgia or even extraction of teeth.
- *Overgrowth of nerve*—it is an overgrowth of severed nerve, attempting to regenerate when the scar tissue or malalignment of a fractured nutrient canal blocks the distal end.
- *Unorganized collection of nerve fibers*—proliferating nerve forms unorganized collection of nerve fibers, composed of varying proportion of axons, perineural connective tissue and Schwann cells.

Clinical Features

- *Age and sex distribution*—it can occur at any age and it is more common in females.
- *Site*—it typically occurs near the mental foramen, on the alveolar ridge in edentulous areas or on the lips and tongue.
- *Appearance*—it appears as a small nodule or swelling of the mucosa.
- *Symptoms*—due to the pressure applied by enlargement of the tangled mass in its bony cavity, severe pain may be experienced. It may have reflex neuralgia with pain referred to the eye, face and head.

- *Size*—it is a slow growing reactive hyperplasia that seldom becomes large, rarely with an excess of 1 cm in diameter.

Radiographic Features

- *Site*—in mandible it is associated with the mandibular canal. In maxilla, it is seen in anterior maxilla.
- *Radiodensity*—it is seen as a destructive lesion. It appears as a radiolucent area.
- *Margins*—it has got well defined and corticated borders (Fig. 15-49).
- *Inferior alveolar nerve canal*—some expansion of the canal is seen.

Fig. 15-49: Neuroma seen in mandible in inferior alveolar canal region as well defined and corticated margin.

Diagnosis

- *Clinical diagnosis*—severe pain, nodule in mental foramina area with history of extraction will aid in diagnosis of traumatic neuroma.
- *Radiological diagnosis*—radiolucent lesion in the mandibular region with corticated border.
- *Laboratory diagnosis*—biopsy shows mass of irregular and interlacing neurofibrils and Schwann cells, situated in connective tissue stroma of either scanty or plentiful proportion.

Differential Diagnosis (Radiological)

- *Odontogenic cyst*—when an individual has painful or extremely sensitive cyst-like radiolucency in the bone with the history of fracture or surgery, neuroma is suspected.

Management

- *Surgical excision*—simple excision of nodule along with proximal portion of the involved nerve.

Palisaded Encapsulated Neuroma

It is also called as 'solitary circumscribed neuroma'. It is reactive lesion rather than true neoplasm.

Clinical Features

- *Age and sex distribution*—it is more commonly seen in fifth and seventh decade of life with no sex distribution.
- *Site*—nose, cheek and intraorally hard palate is common site.
- *Appearance*—it has smooth surface, painless, dome shaped papule or nodule.
- *Size*—it is less than 1 cm in diameter.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Laboratory diagnosis*—biopsy shows interlacing fascicles of spindle that consist of Schwann cells. Nuclei are wavy and pointed. Palisading and Verocay bodies of Antoni A cells are present.

Management

- *Surgical excision*—conservative surgical excision should be done.

Ganglioneuroma

It is same like neuroblastoma, but in it, differentiated cells are numerous. It grows less rapidly than the neuroblastoma and when fully differentiated, it depicts benign characteristic. The fully differentiated ganglioneuroma is composed of cells that are very much like the normal cells. Numerous nerve fibers and well differentiated nerve bundles are present.

Melanotic Neuroectodermal Tumor of Infancy

It is also called previously as 'pigmented ameloblastoma', 'melanoameloblastoma', 'melanotic ameloblastoma', 'retinal anlage tumor', and 'melanotic progonoma' due to possible source of tumor from odontogenic epithelium. Nowadays, these terms are not used as it is proved that tumor is of neural crest in origin.

Clinical Features

- *Age and sex*—it occurs in infants under the age of six months, with equal sex distribution.
- *Site*—maxilla is more commonly affected than mandible. It is more common in anterior region.
- *Symptoms*—it is symptomless tumor.
- *Appearance*—it is rapidly growing, non-ulcerated, darkly pigmented lesion. It is blue black in color.

Radiological Features

- *Radiodensity*—there may be well defined areas of radiolucency. Destruction of underlying bone occurs.
- *Margins*—margins of these lesions are irregular.
- *Teeth*—displacement of developing teeth is present.
- *Sunray appearance*—in some cases there may be osteogenic reaction giving sunray appearance.

Diagnosis

- *Clinical features*—blue black mass in anterior maxilla in infant will give clue to diagnosis.
- *Laboratory diagnosis*—high urinary level of vanillyl-mandelic acid (VMA). Biopsy shows both pigmented and non-pigmented cells.

Management

- *Surgical removal*—conservative surgical excision should be carried out. Recurrence is extremely low.

Muscle Tumors

Leiomyoma

It is a benign tumor derived from smooth muscle and is found in a variety of anatomic sites like skin and subcutaneous tissues. It can be solid leiomyoma, vascular leiomyoma and epithelioid leiomyoma.

Clinical Features

- *Age and sex*—it occurs in middle decades of life. Males are affected more commonly than females.
- *Site*—it usually occurs in uterus. It is uncommon in oral cavity due to general absence of smooth muscles except in blood vessel walls and circumvallate papillae of tongue. The smooth muscle of the arrectores pilorum may be a source of cheek tumor.
- *Symptoms*—the patient may complain of sore throat or tumor in the throat. In some cases, there may be pain.
- *Appearance*—it is a slow growing, painless lesion, which is superficial and often pedunculated.
- *Size*—in most of the cases, the lesion is small.
- *Color*—it does not ulcerate and resembles the normal mucosa in color and texture. In case of vascular leiomyomas it can exhibit bluish hue.

Diagnosis

- *Clinical diagnosis*—it has got no typical clinical features.
- *Laboratory diagnosis*—biopsy shows interlacing bundles of smooth muscle fibers, interspersed by varying amounts of fibrous connective tissue.

- *Angioleiomyoma*—in some cases, origin from the blood vessels is obvious since the vessels are enlarged with thick muscular walls, around which the tumor muscle fibers are dispersed in a circular manner. It is called as angioleiomyoma or angiomyoma.
- *Angiomyolipoma*—rarely, angiomyoma may contain adipose tissue: then it is called as angiomyolipoma.

Management

- *Surgical excision*—it is treated by conservative surgical excision of the tumor.

Rhabdomyoma

It is a benign tumor of striated muscle origin. It is an exceedingly rare lesion.

Clinical Features

- *Age*—most commonly occurs in 5th decade of life with male to female ratio of 2:1.
- *Site*—it mostly occurs in head and neck region. The most common sites of occurrence, intraorally, are the floor of the mouth, tongue, soft palate, buccal mucosa and lower lip.
- *Symptoms*—it is painless and slow growing. Laryngeal and pharyngeal lesion may lead to airway obstruction.
- *Appearance*—it presents a well circumscribed tumor mass which may have a known duration of months or even several years.

Diagnosis

- *Clinical diagnosis*—it has got no typical clinical features.
- *Laboratory diagnosis*—the nucleus is vesicular and cells with several nuclei are sometimes seen.
- *Adult's type*—in adult type, the tumor is composed of large, round cells that have granular, eosinophilic cytoplasm and show irregular cross striations. The cytoplasm is rich in glycogen and glycoprotein.
- *Fetal*—fetal type is characterized by immature skeletal muscles in varying stages of development and undifferentiated mesenchymal cells.

Management

- *Surgical excision*—it is excised conservatively usually enucleating with ease.

Granular Cell Tumor

It is also called as '*myoblastic myoma*', '*granular cell myoblastoma*' and '*granular cell schwannoma*'.

Origin

- *Striated muscle*—it may be derived from striated muscles. But, these tumors may be found in areas like breast and skin, where the striated muscles are absent.
- *Neural theory*—in neural theory it is proposed that these tumors are derived from the connective tissue of nerves and hence was called as '*granular cell neural fibroma*'.
- *Stem cells*—some authors state that it is derived from stem cells with a leiomyofibrillogenic capacity, which may be some type of specialized smooth muscle cells peculiar to certain tissue, that are found in characteristic sites of the tumor.

Clinical Features

- *Age and sex*—it can occur at any age and females are affected more commonly than males.
- *Site*—most common site of occurrence is dorsum of tongue followed by skin, lips, breast, subcutaneous tissue, vocal cord and floor of mouth.
- *Appearance*—lesion which is found on tongue is usually single firm, submucosal nodule within the substance of the tongue itself.
- *Size*—the size of the tumor varies from a few millimeters to few centimeters.
- *Color*—color is usually pink but some tumor may appear yellow in color.
- *Signs*—lesion is not ulcerated and may have normal covering or may exhibit some clinical leukoplakia.

Diagnosis

- *Clinical diagnosis*—submucosal swelling on the dorsum of tongue may give clue to diagnosis (**Fig. 15-50**).
- *Laboratory diagnosis*—the lesion is composed of two types of cells: granular cells and satellite cells. The large granular cells are called as *Abrikossoff myocytes*.

Fig. 15-50: Submucosal nodule seen on tongue in granular cell myoblastoma.

Management

- *Surgical excision*—it is best treated by conservative local excision of the tumor.

Giant Cell Neoplasm

Central Giant Cell Tumor

It is the term applied for the lesions, which contain giant cells. It is chiefly a tumor of long bones, occurring at the epiphyseal end involving the adjacent metaphysis. It is an extremely uncommon tumor of head and neck and creates a lot of confusion with respect to diagnosis. Today these tumors represent benign tumors of osteoclastic origin.

Origin of Giant Cells

Different theories are given to describe the origin of giant cells in these lesions:

- *Resorption of deciduous roots*—Giant cells might be derived from the proliferating giant cells associated with the resorption of deciduous tooth roots. But for this, association of the lesion in transition period i.e. from of deciduous to permanent tooth should be there: but such association is found only in few cases.
- *Endothelial cells of capillaries*—another theory states that it originates from the endothelial cells of capillaries. To support this theory: there is a common occurrence of giant cells in vascular channels, suggesting that they arise from endothelial cells.
- *Modified form of cells*—Sapp found that giant cells, ultrastructurally, contain a sufficient number of features in common with osteoclasts. This concludes that they represent a slightly modified form of the cells.

Clinical Features

- *Age and sex distribution*—it is most frequently seen in 3rd and 4th decades, it is unusual in patients less than 20 years. Women are more affected as compared to males.
- *Site*—the commonest sites for giant cell tumor are the lower end of the femur, upper end of the tibia and lower end of the radius. In the oral cavity it is rare and if found it is in jaw.
- *Symptoms*—the principal symptoms are swelling of the bone accompanied in some cases by pain. The color of lesion is blue due to its cortical and mucosal thinning and internal vascularity (**Fig. 15-51**).
- *Signs*—the swelling may be tender and egg shell crackling can be elicited in large tumors. There is also expansion of jaw which is painless.

Fig. 15-51: Bluish color of central giant cell tumor shows its vascular nature (Courtesy Dr Tapasya Karamore).

Radiological Features

- *Radiodensity*—there is an area of radiolucency with thinning and expansion of the cortex, with little or no periosteal new bone formation.
- *Appearance*—the radiolucent area may show soap bubble or honeycomb appearance but this is inconsistent. Thinning of cortices is also present (**Fig. 15-52**).
- *Effect on teeth*—there may be resorption of roots of tooth. Displacement of teeth can also occur.

Fig. 15-52: Thinning of cortex seen in central giant cell tumor (Courtesy Dr Parate).

Diagnosis

- *Clinical diagnosis*—bluish color vascular lesion may suspect central giant cell tumor.
- *Radiological diagnosis*—multilocular lesion with thin cortex will give clue to diagnosis.
- *Laboratory diagnosis*—the tumor forms a maroon or reddish brown fleshy mass that replaces the spongiosa of the bone. It consists of numerous giant cells lying in cellular matrix composed of spindle shaped cells and scanty collagen.

Management

- *Curettage*—the usual method of treatment is curettage, but this is followed by a high recurrence rate.
- *Intralesional corticosteroid*—nowadays, intralesional injection of corticosteroids proves to be beneficial in many cases. Suggested use of triamcinolone 10 mg/ml of once in week for 6 weeks. 1 ml injection is given for each 1 cm of jaw involvement. Local anesthesia is added in the injection.

Peripheral Giant Cell Granuloma

It is also called as '*peripheral giant cell reparative granuloma*', '*giant cell epulis*', '*osteoclastoma*' and '*peripheral giant cell tumor*'. It is five times more common as compared to central giant cell granuloma. It seems to originate from either periodontal ligament or mucoperiosteum.

Etiology

- *Injury*—it is an unusual response of tissue to injury. The trauma may be caused by tooth extraction and dental irritation.
- *Chronic infection*—it can occur in chronic infections.
- *Hormonal*—it may appear under the stimulus of increased circulating parathormone i.e. primary and secondary hyperparathyroidism.

Clinical Features

- *Age and sex distribution*—most oftenly seen over 20 years of age, with an average of 45 years. Females are affected twice as common as males. Predominant in white persons.
- *Common site*—it occurs on gingiva and alveolar mucosa, most frequently anterior to molars. It is common in mandible than maxilla.
- *Early lesion*—it appears as discoloration and slight swelling of the buccal aspect of the gingiva.
- *Later lesion*—the lesion increases in size and becomes rounded and very often pedunculated (**Fig. 15-53**).
- *Hourglass appearance*—sometimes, it grows in an hourglass manner, with the waist of the lesion between two teeth and the globular extremities presenting buccally and lingually (**Fig. 15-54**).
- *Color*—the color of the lesion is usually dark red (**Fig. 15-55**) or maroon color. If sufficient amount of hemosiderin exists near the periphery, the lesion is bluish, otherwise it is red and/or pink. Lesions with much fibrous tissue are paler.
- *Consistency*—it may feel soft to hard.
- *Size*—the lesions vary in size from 0.5 cm to 1.5 cm in diameter.

Fig. 15-53: Rounded lesion of peripheral giant cell granuloma seen on gingiva.

Fig. 15-54: Peripheral giant cell granuloma showing hourglass appearance.

Fig. 15-55: Dark red color of peripheral giant cell granuloma seen in buccal sulcus.

- *Signs*—it is vascular or hemorrhagic and sometimes ulceration is also present. There may be tenderness on palpation.
- *Edentulous area*—in edentulous patients, it may present as a vascular, ovoid or fusiform swelling of the crest of the ridge, seldom over 1-2 cm in diameter or there may be granular mass of tissue which seems to be growing from the tissue covering the slope of the ridge.

Radiological Features

- *Edentulous area*—in edentulous areas, the peripheral giant cell granuloma characteristically exhibits superficial erosion of the bone with peripheral 'cupping' of the bone.
- *Dentulous area*—in dentulous areas, there may be superficial destruction of the alveolar margins or crest of the interdental bone.

Diagnosis

- *Clinical diagnosis*—dark red color lesion with hourglass appearance soft in consistency will favor the diagnosis of peripheral giant cell granuloma.
- *Laboratory diagnosis*—multinucleated giant cells and young connective tissue spindle shaped cells are scattered throughout the granulation tissue in delicate reticular and fibrillar connective tissue stroma.

Differential Diagnosis

- *Hemangioma*—present at birth, seldom occurs on gingiva.
- *Lymphangioma*—it is rare on gingiva and color is same as the tissue.
- *Metastatic carcinoma*—history of primary tumor.
- *Oral nevi and nodular melanoma*—firm on palpation and darker in color.

Management

- *Surgical excision*—excision with borders of normal tissue with entire base of the lesion, so that recurrence is avoided.
- *Removal of cause*—elimination of chronic irritant.

Teratoma

It is also called as 'teratoblastoma' or 'teratoid tumor'. It is a neoplasm of different types of tissue which are not native to the area in which the tumor occurs. True teratoma is developmental tumor which is composed of all the three germ layers ectoderm, mesoderm and endoderm. Out of these three layers, one of the layers exhibits neoplastic proliferation.

It is congenitally acquired and usually found in the ovary. The finding of various organs like structure i.e. teeth,

tissue, hair and skin are seen in this tumor. The lesion that arises in the base of the skull often extends into the cranial and oral cavity; newborn infants with such lesions rarely survive.

Clinical Features

- *Age*—it is known to be present at birth or is discovered shortly thereafter.
- *Site*—it can occur in ovaries, testes, anterior mediastinum, retroperitoneal area, presacral and coccygeal regions, pineal region, head, neck and abdominal viscera. In oral cavity it can be seen on hard palate and soft palate area.
- *Symptoms*—they are benign lesions and grow slowly.
- *Signs*—they often contain recognizable hair, sebaceous material and teeth.

A

B

Figs 15-56A and B: (A) Child patient with appearance of double palate. (B) Same patient after 2 years showing double arch and double palate (Courtesy Dr Debta).

Fig. 15-57: Radiograph of same patient showing double arch and double palate appearance (Courtesy Dr Debta).

- *Epignathus*—true teratoma occurs sometimes and it is called as '*epignathus*'. It arises from the hard and soft palate which may be perforated. The tumor tends to fill the buccal cavity and may extend into the mouth. Epignathi may develop in the region of Rathke's pouch and may be found entirely above the palate or even within the cranium. In rare cases, grapefruit size of tumor protruding from the mouth may arise from the palate and can be a well formed finger with a finger nail on its upper part.
- *Double palate*—this is a rare type of teratoma which occurs in hard palate area. There is occurrence of double palate with double arch in the palate area (**Figs 15-56 A and B**). Double palate can also be seen on panoramic radiograph (**Fig. 15-57**).

Diagnosis

- *Clinical diagnosis*—it is not difficult to make clinical diagnosis as tissue present in teratoma is not of that particular site.
- *Laboratory diagnosis*—biopsy shows epithelium and epithelial appendages such as hair, sweat gland, sebaceous glands, salivary glands and teeth as well as discrete epithelial organs such as thyroid gland and pancreas.

Management

- *Surgical*—surgical removal of the tumor should be carried out.

Salivary Gland Tumor

It is discussed in Chapter 26: *Salivary Gland Disorders*.

Inflammatory Hyperplasia

Chronic injury produces inflammation, which in turn stimulates the formation of granulation tissue that consists of proliferative endothelial tissue with rich patent

capillary bed, chronic inflammatory cells and few fibroblasts. They are smoothly contoured or lobulated with very red appearance due to rich vascularization and transparency of non-keratinized epithelial covering. It has got soft, spongy and broad sessile base.

Pyogenic Granuloma

It is also called as '*granuloma pyogenicum*'. It is a response of tissues to non-specific infection of staphylococcus or streptococci. It is relatively a common soft tissue tumor of the skin and mucous membrane. It is known to be a reactive inflammatory process in which there is an exuberant fibrovascular proliferation of the connective tissue, secondary to some low grade chronic irritant.

Etiology

- *Microorganisms*—it is usually due to botryomycotic infection, staphylococci and streptococci.
- *Trauma*—it may occur as a result of minor trauma to the tissue, which provides a pathway for the invasion of tissues by non-specific of microorganisms.
- *Local irritant*—it is an inflammatory response to local irritation such as calculus.
- *Hormonal imbalance*—it is a contributing factor for the development of some pyogenic granulomas.

Clinical Features

- *Age and sex*—females are affected more than males with common age of occurrence are 11 to 40 years.
- *Sites*—common sites are gingiva, lip, tongue, buccal mucosa, palate, vestibule and alveolar mucosa.
- *Symptoms*—it is an asymptomatic papular, nodular polypoid mass.
- *Appearance*—lesions are elevated, pedunculated or sessile masses with smooth, lobulated or even warty surface.
- *Surface*—surface can commonly ulcerate and shows tendency to hemorrhage upon slightest pressure or trauma.
- *Pus*—sometimes, there is exudation of purulent material.
- *Color*—it is deep red to reddish purple depending on the vascularity (**Fig. 15-58**); it is painless and rather soft in consistency, with some lesions having brown cast, if hemorrhage has occurred into the tissues. If lesion is of mixed variety it appears red with pink areas and if it is completely fibrous it is slightly pink and firm on palpation.
- *Consistency*—it feels moderately soft and bleeds readily.
- *Size*—it may develop rapidly, reaching full size and remain static for an indefinite period with size ranging from few millimeters to centimeters. Average size of lesion being 0.9 to 1.2 cm.

Fig. 15-58: Pyogenic granuloma presenting as reddish purple mass on gingiva (Courtesy Dr Chole).

Diagnosis

- *Clinical diagnosis*—reddish purple lesion, soft in consistency can be pyogenic granuloma.
- *Laboratory diagnosis*—biopsy shows granulation tissue which is exuberant and is usually localized. Overlying epithelium, if present, is generally thin and atrophic, but may be hyperplastic.

Differential Diagnosis

- *Small benign and malignant mesenchymal tumor*—higher incidence of pyogenic granuloma.
- *Exophytic capillary hemangioma with ulceration*—most of the hemangiomas are blanched on pressure while pyogenic granuloma does not blanch on pressure.
- *Peripheral giant cell granuloma*—lesion is more bluish, as compared to pyogenic granuloma which is red to pink. There is also radiological evidence of superficial cuffing of the alveolar bone.
- *Peripheral fibroma with calcifications*—underexposed radiograph shows small radiopaque foci within the shadow of growth.

Management

- *Surgical excision*—surgical excision is done and care is taken to remove the calculus of adjacent teeth as it may act as a local irritant and cause recurrence.
- *Removal of irritant*—elimination of the causative agent should be done.

Pregnancy Tumor

Pregnancy tumor usually develops in first trimester of pregnancy. The size usually increases in 7 months of pregnancy (Fig. 15-59).

Fig. 15-59: Pregnancy tumor present as growth in upper maxillary lesion (Courtesy Dr Abhishek Soni).

Etiology

- *Local minor trauma*—it occurs as a result of local minor trauma and in cases where tissue reaction is intensified by endocrine alteration occurring during pregnancy.

Clinical Features

- *Age*—it occurs during pregnancy, often in about 3rd month of pregnancy and sometimes later.
- *Appearance*—it is a well defined lesion, which gradually increases in size (Fig. 15-60).
- *Regression after pregnancy*—maximum cases of pregnancy tumor regress after pregnancy. If surgically removed during pregnancy, it usually recurs.

Fig. 15-60: Well defined lesion seen in 3rd trimester of pregnancy (Courtesy Dr Abhishek Soni).

Radiological Appearance

- *Rarefaction of bone*—in some of the cases there is slight rarefaction of the bone beneath the attachment of the tumor, usually at the crest of the alveolus.

Diagnosis

- *Clinical diagnosis*—well defined tumor-like lesion in pregnancy will diagnose this condition.
- *Radiological diagnosis*—not so specific.
- *Laboratory diagnosis*—biopsy shows similar feature as that of pyogenic granuloma.

Management

- *No treatment*—no treatment should be given to patient as maximum cases regress by its own after pregnancy.
- *Surgical excision*—if pregnancy tumor does not resolve after pregnancy, it should be surgically excised.

Parulis

It is a small inflammatory hyperplastic type of lesion that develops on the alveolar mucosa at the oral terminal of draining sinus (**Fig. 15-61**). Maxillary labial and buccal mucosa are commonly affected. Slight digital pressure on periphery of parulis may force a drop of pus from the sinus opening. It usually regresses after the infection is eliminated.

Fig. 15-61: Parulis presented as hyperplastic growth at the sinus opening of maxillary premolar region.

Inflammatory Papillary Hyperplasia

It is also called as 'palatal papillomatosis' and 'palatal epithelial hyperplasia'. It occurs in 3% to 4% of dentures wearers.

Etiology

- *Frictional irritation*—it is produced by loose fitting dentures on palatal tissues. It occurs in patients who sleep with their dentures. It is much common in acrylic dentures than in those with metallic dentures.

- *Suction chamber in palatal seating*—full dentures in which relief areas or suction chambers are cut in palatal seating surface appear to be the strongest stimuli for the lesion.
- *Poor denture hygiene*—it is more common in patients with poor oral hygiene.
- *Amalgam filling irritation*—in some cases, irritation due to amalgam filling may produce these lesions.

Clinical Features

- *Age and sex*—It can arise at any age in adults and has no definite sex predilection.
- *Site*—it occurs exclusively on palate beneath the complete or partial denture. It occurs predominately in edentulous patients and the site of lesion corresponds to the denture base. In rare cases, cheek may be involved.
- *Appearance*—whole palatal mucosa under the denture may be covered with numerous small polypoid masses.
- *Warty appearance*—the lesion presents as numerous closely arranged, red, edematous papillary projections (**Fig. 15-62**) often involving nearly all of the hard palate and imparting it to a 'warty appearance'.

Fig. 15-62: Inflammatory papillary hyperplasia showing papillary projection (Courtesy Dr Bande).

- *Overripe berry appearance*—in some cases, it is swollen and papillary projection resembles the surface of 'overripe berry'.
- *Cobblestone appearance*—in some cases, it produces a 'cobblestone' appearance (**Fig. 15-63**).
- *Signs*—lesions are friable, often bleed with minimum trauma and may be covered with thin whitish exudate. The tissue exhibits varying degrees of inflammation, but seldom there is ulceration.
- *Size*—these are seldom over 0.3 cm in diameter. The lesion may extend onto the alveolar mucosa. The individual papillae are seldom over a millimeter or two in diameter.

- *Candida infection*—when complicated by *Candida albicans*, lesion appears as red to scarlet, soft and bleeds easily in the inflammatory or granulomatous stage.

Fig. 15-63: Palatal papillary hyperplasia showing cobblestone appearance.

Diagnosis

- *Clinical diagnosis*—papillary projection beneath the palatal denture will diagnose this lesion.
- *Laboratory diagnosis*—biopsy shows numerous small vertical projections, each composed of parakeratotic or sometimes orthokeratotic stratified squamous epithelium and a central core of connective tissue.

Differential Diagnosis

- *Nicotina stomatitis*—Occurs almost exclusively in pipe smokers who are not wearing maxillary complete dentures. Lesions are more nodular and broader but less elevated. Red dot is seen in center.
- *Verrucous carcinoma*—papillary hyperplasia may mimic verrucous carcinoma. But here the papillary hyperplasia is not associated with denture. Biopsy should be done to rule out verrucous carcinoma.

Management

- *Removal of denture*—remove the denture at night to provide rest to the tissue. In many cases tissue will resume normal appearance after denture is removed.
- *Conditioning liner*—conditioning liner should be applied under the denture. This will act as palatal dressing and promotes greater comfort.
- *Topical antifungal treatment*—in case with superimposed candidal infection, topical application of antifungal agents should be used. Most commonly used is nystatin ointment.

- *Surgical removal*—it is done by partial thickness or full thickness surgical blade excision, curettage, electrosurgery and cryosurgery. This is done in case of fibrosis of the tissue.

Epulis Granulatosum

It is reactive hyperplasia that develops within a tooth socket after the extraction or exfoliation of tooth. It is caused by sharp spicules of bone in socket.

Clinical Features

- *Age*—it can occur at any age and becomes apparent within 2 weeks after the loss of a tooth.
- *Appearance*—it is exuberant dark red granulation tissue extruding from the socket (Figs 15-64A and B).
- *Symptoms*—it is painless growth.
- *Signs*—the enlargement is soft, hemorrhagic with an erythematous to white, smooth surface.

Figs 15-64A and B: Epulis granulatosum showing growth in the extraction socket.

Diagnosis

- *Clinical diagnosis*—hyperplasia in extraction socket will be diagnosed this condition.

Differential Diagnosis

- *Antral polyp*—sinus wall defect is usually demonstrated either radiographically or by requesting the patient to blow air through the nose while nostrils are occluded.
- *Pulp polyp*—extensive destruction of tooth can be seen.
- *Malignancy*—radiological changes are present.

Management

- *Curettage*—it is done to remove the granulation tissue and smoothing of the socket borders is indicated.
- *Excisional biopsy*—it should be done.

Nodular Fasciitis

It is also called as '*pseudosarcomatous fasciitis*'. It is non-neoplastic connective tissue proliferation. It histologically mimics malignant mesenchymal neoplasm but its clinical behavior is benign. It appears to be an inflammatory reactive phenomenon.

Clinical Features

- *Age and sex distribution*—it is more commonly seen in 4th and 5th decade of life. There is no sex predilection.
- *Site*—it is more common on the trunk and extremities. Intraorally, it is seen on buccal mucosa followed by subcutaneous tissues overlying the mandible, zygoma, parotid sheath and oral mucosa.
- *Symptoms*—it appears as a small lump, which may be painful.
- *Sign*—it has got exophytic presentation.
- *Size*—the lesion often enlarges rapidly, but only to maximum size of 4 cm, where it remains stationary or regresses.

Diagnosis

- *Clinical diagnosis*—it is not specific.
- *Laboratory diagnosis*—biopsy shows proliferation of fibroblast in haphazard manner in a vascular myxoid matrix which is rich in acid mucopolysaccharide. It results in a loose textured feathery appearance. There is frequent patchy chronic inflammatory infiltration, consisting of lymphocytes and occasional plasma cells and macrophages.

Management

- *Surgical excision*—local excision will yield excellent result.

16

Malignant Tumor of Jaw

Oral Carcinoma

Oral carcinoma is one of the most prevalent cancers and is one of the 10 major causes of death. Most common oral carcinoma is squamous cell carcinoma. It is a disease of increasing age with 95% cases in people older than 40 years of age.

Cancer is a commonly used term for all malignant tumors. In Latin language, cancer means 'crab' which has a fat meaty body and mass extension which springs and invades the surrounding tissues.

Cancer may be defined as an uncontrolled tissue growth in susceptible patient, which results from imbalance between cell division and programmed cell death.

Tumor is an autonomous new growth of tissue or it is an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of normal tissue and persists in

the same excessive manner even after the cessation of stimuli which evoked the changes.

It is classified in **Table 16-1**.

Characteristics of Malignant Lesion

- *Lesion borders*—they exhibit ill defined borders which are very irregular and ragged.
- *Rapid growth*—it increases in size very rapidly.
- *Metastasis*—they always metastasize either by direct spread, by lymphatics or through the bloodstream.
- *Adjacent cortical bone*—grows by invasion and causes destruction of adjacent structures. Bony cortex will be destroyed rather than expanded.
- *Radiodensity*—radiolucent or may be mixed with radiopacity.
- *Dental involvement*—root intact and tooth in position.

Table 16-1: Classification of malignant tumor

Epithelial • Squamous cell carcinoma • Metastatic carcinoma • Basal cell carcinoma • Transitional cell carcinoma • Malignant melanoma • Verrucous carcinoma • Spindle cell carcinoma • Primary intra-alveolar carcinoma • Intraepidermoid carcinoma • Adenoid squamous cell carcinoma Fibrous connective tissue • Fibrosarcoma • Malignant fibrous histiocytoma Adipose tissue • Liposarcoma Cartilage • Chondrosarcoma Bone • Osteosarcoma • Osteochondrosarcoma • Ewing's sarcoma Vascular • Hemangioendothelioma • Angiosarcoma	Neural tissue • Neurosarcoma • Neurofibrosarcoma • Neuroblastoma • Ganglioneuroma Muscle • Leiomyosarcoma • Rhabdomyosarcoma • Malignant granular cell myoblastoma Lymphoid tissue • Hodgkin's lymphoma • Non-Hodgkin's lymphoma • Primary reticular cell sarcoma • Burkitt's lymphoma • Leukemia Myeloma • Multiple myeloma • Plasmacytoma Tumor of salivary gland • Mucoepidermoid carcinoma • Adenocystic carcinoma • Adenocarcinoma • Acinic cell carcinoma • Malignant changes in pleomorphic adenoma
---	---

Etiology and Risk Factors for Oral Cancer (Fig. 16-1)

Tobacco Use

Smokeless tobacco

- *Major etiological factors*—tobacco use is the major etiological factor for the development of oral cancer. The effect of tobacco use, heavy alcohol consumption and poor diet can probably explain over 90% of cases of oral cancer. Much of tobacco in the world is consumed without combustion, by being placed in contact with mucous membrane, through which nicotine is absorbed.
- *Why it causes oral cancer*—it contains potent carcinogens like nitrosamine, polycyclic hydrocarbons and polonium and metabolites of these constituents, which have been suggested etiologic factors in oral cancer.
- *Common forms of oral smokeless tobacco*—it includes *pan/ paan/betal quid* (it contains areca nut, betel leaf, slaked lime, catechu, condiments with or without tobacco), *khaini* (contains tobacco and lime), *mishri* (burned tobacco), *zarda* (boiled tobacco), *gadakhu* (tobacco and molasses), *mawa* (tobacco, lime and areca), *nass* (tobacco, ash, cotton or sesame oil), *naswar/niswar* (tobacco, lime, indigo, cardamom, oil and menthol), *shammah* (tobacco, ash and lime) and *toombak* (tobacco and sodium bicarbonate).

Smoking

- *Why it causes oral cancer*—tobacco smoke contains carbon monoxide. It is an important factor in the development of oral cancer. Study shows that cigar and pipe smoking increase the risk of cancer than cigarette smoking.
- It has been stated that the pooling of carcinogens in saliva gives rise to cancer in the floor of mouth and ventral and lateral tongue.
- Smoking is strongly associated with soft palate cancer than anterior sites.

Fig. 16-1: Etiology of oral cancer diagrammatic representation.

Alcohol

- *Forms of alcohol*—all forms of alcohol; including hard liquor, wine and beer has been implicated in the etiology of oral cancer.
- *Mechanism*—the mechanism by which alcohol affects includes the dehydrating effect of alcohol on the mucosa which increases mucosal permeability and the effects of carcinogens on the mucosa. Beverage congeners include nitrosamines and impurities which can act as carcinogens.
- *Associated habit*—most of the heavy alcohol consumers use tobacco, so it is very difficult to separate the ill effects individually.

Actinic Radiation

It is a minor etiologic factor in case of lip cancer. Lip cancer occurs more commonly in fair skinned people who are generally engaged in outdoor occupation, such as farming and fishing.

Familial and Genetic

There is little evidence that there is familial and genetic predisposition for the development of oral cancer.

Lip cancer is amongst the sites which show strongest cancer clustering within families. But it also reflects the fact that families tend to have same occupation, i.e. fishing and farming, which is related with ultraviolet exposure.

Oral cancers are more prevalent in blacks as compared to white.

Atmospheric Pollution

Parts of the urban/rural difference in incidence of head and neck cancers have been related to atmospheric pollution.

Sulphur dioxide and smoke concentration in the atmosphere are positively correlated with squamous cancer of larynx and pharynx. The impact on cancer of the mouth is likely to be less, but merits careful study.

Blue collar workers exposed to dust or inhalation of organic and inorganic agents are at increased risk of cancers of mouth.

Orodental Factors

It is more prevalent in patients with poor oral hygiene, faulty restorations, sharp teeth, ill fitting dentures and those with syphilitic glossitis.

Vitamin A Deficiency

Vitamin A deficiency can produce excessive keratinization of the skin and mucous membrane. So their deficiency can predispose to the formation of carcinoma.

Immunity

The increasing incidence of oral cancers is clearly age related, which may reflect declining immune surveillance with age.

It may occur in immunosuppressed patients following organ and bone marrow transplantation. HIV/AIDS patients are at increased risk of oral cancer.

Syphilis

It is traditionally associated with oral cancer. Oral malignancy is commonly found in tertiary stage of syphilis. Another aspect why syphilis can lead to malignancy is that in the management of syphilis previously we use arsenic and heavy metal which has potential carcinogen.

Diet Deficiency and Deficiency Status

Nutritional deficiency and liver dysfunction can also play a role in it. The relationship between sideropenic dysphagia and oral cancer is well established.

Ionizing Radiation

Carcinoma of buccal mucosa may occur as a complication of long-term radiotherapy.

Trauma

Trauma in combination with other factors like chronic cheek biting, denture use and irregular teeth may act as a co-carcinogen and may promote transformation of epithelial cells.

Virus

The possibility of type I herpes simplex virus being associated with oral cancer has been suggested.

Other viruses which can lead to oral cancer are human papillomavirus and human immunodeficiency virus.

Intraoral Lesions

- *Chronic ulceration and fissure*—it can cause oral cancer particularly of lip.
- *Lichen planus*—reports of carcinoma supervening on lichen planus have been made in some cases.
- *Candidiasis*—it is possible precursor of carcinoma. Candidal infection is often associated with acanthosis and parakeratosis.
- *Leukoplakia*—it is common pre-malignant condition seen in oral cavity. Nodular leukoplakia show higher rates of epithelial dysplasia.
- *Median rhomboid glossitis*—in some cases, it has followed by cancer.

- *Plummer Vinson's syndrome*—the atrophic changes in the mucous membrane of the upper alimentary tract that occur in this syndrome may predispose to malignancy.
- *Submucous fibrosis*—it is precancerous condition occurs in oral cavity.
- *Oral melanosis*—it appears to be associated with oral cancers in India.
- *Discoid lupus erythematosus*—a number of cases of carcinoma of lip developing in the lesion of lupus erythematosus have been reported.
- *Epidermolysis bullosa*—it is occasionally followed by carcinoma.

Epithelial Tumors

Peripheral Squamous Cell Carcinoma

It is also called as '*epidermoid carcinoma*' or '*epithelioma*'. It represents 90% of all malignant tumors occurring in the mouth and jaws. The majority of oral cancer cases are of squamous cell carcinoma. The oral lesion often invades the jaw. It arises in gingival tissue, buccal sulcus, floor of mouth and some other portion of oral mucosa.

Clinical Features

General features

- *Age and sex*—predominately, it occurs in males with ratio of 2:1, older than 50 years with an average age of approximately 60 years.
- *Site*—most commonly involved are the posterior and lateral borders of the tongue and lower lip and less frequently the floor of mouth, alveolar mucosa, palate and buccal mucosa. It may be solitary and multifocal.
- *Symptoms*—patient may present with awareness of a mass in the mouth and neck. Small lesion is asymptomatic. Large lesions may cause some pain or paresthesia and swelling. Patients complain of persistent ulcer in the oral cavity. Function of organ in which malignancy occur is impaired.
- *Appearance*—the clinical appearance of a carcinomatous ulcer is that one of irregular shape (**Fig. 16-2**), indurated and raised everted edges.
- *Base*—usually have broad base and are dome-like or nodular. Base is firm on palpation.
- *Exophytic lesion*—it has irregular, fungating, papillary and verruciform surface. The surface is ulcerated and base is hard on palpation (**Fig. 16-3**).
- *Endophytic lesion*—this is depressed irregularly shaped ulcerated central area with surrounding rolled border. The rolled border results from invasion of tumor in the tissue (**Fig. 16-4**).

Fig. 16-2: Irregular shaped ulceration seen in buccal vestibule due to malignancy (Courtesy Dr Chole).

Fig. 16-4: Endophytic type of growth seen in carcinoma of palate which shows rolled border (Courtesy Dr Suwas Darvekar).

Fig. 16-3: Exophytic growth seen in malignancy showing irregular margins and surface ulceration (Courtesy Dr Suwas Darvekar).

Fig. 16-5: Surface of oral malignancy is whitish gray and pebbly (Courtesy Dr Parate).

- **Surface**—surface may range from granular to pebbly to deeply creviced (**Fig. 16-5**). In some cases, surface may be entirely necrotic and have ragged whitish gray appearance.
- **Color**—it may be completely red or red surface may be sprinkled with white necrotic or keratin area.
- **Lymph nodes**—superficial and deep cervical nodes are commonly affected. They become enlarged and are firm to hard on palpation. The nodes are non-tender unless associated with secondary infection or an inflammatory response. It may be nodular or polypoid and pink to red and have at least one ulcerated patch on their surface. Fixation of nodes to adjacent tissues occur later.

- **Effect on adjacent tissues**—fixation of primary tumor to adjacent tissues, i.e. overlying bone suggests involvement of periosteum and possible spread to bone.
- **Field cancerization**—tendency of development of multiple mucosal cancers, is called as field cancerization. This occur due to diffuse exposure of local carcinogen.

Carcinoma of floor of mouth

- **Site**—most frequently in the anterior portion of floor.
- **Appearance**—the typical carcinoma of the floor of mouth is an indurated ulcer of varying size, on one side of the midline (**Fig. 16-6**). It may take form of wart-like growth, which tend to spread superficially rather than in depth.
- **Symptoms**—it may or may not be painful. In some cases, there may be referred pain in the ears. The proximity of this tumor to the tongue produces some restricted/limited movements of tongue, often induces peculiar thickening

Fig. 16-6: Carcinoma involving floor of mouth showing indurated ulceration.

or slurring of the speech. There may be excessive salivation.

- *Teeth mobility*—carcinoma in close relation to teeth may cause loosening or exfoliation and root resorption.
- *Extent*—carcinoma of floor of mouth may invade the deeper tissues and may even extend into the sub-maxillary and sublingual glands.
- *Metastasis*—metastasis from the floor of the mouth are found most commonly in the sub-maxillary group of lymph nodes and since the primary lesion frequently occurs near the midline where lymphatic cross drainage exists, contralateral metastasis is often present.

Carcinoma of buccal mucosa (Figs 16-7A and B)

- *Site*—the lesions develop most frequently along or inferior to a line opposite the plane of occlusion. It usually occurs opposite to the third molar.
- *Symptoms*—the lesion is often painful.
- *Appearance*—the tumor begins as small nodules and enlarges to form a wart-like growth which ultimately ulcerates (**Fig. 16-8**).
- *Extent*—there is induration and infiltration of deeper tissues. Extension into the muscle of neck, alveolar mucosa and ultimately into bone may occur.
- *Exophytic growth*—some cases appear to be growing outward from the surface rather than invading the tissues is called as exophytic or verrucous growth.
- *Metastasis*—the most common site of metastasis is the submaxillary lymph nodes.

Carcinoma of labial mucosa

- *Cause*—it is frequently encountered in person who habitually keeps a mixture of tobacco lime in the labial vestibule.
- *Site*—the lower labial mucosa is more commonly involved than the upper.
- *Symptoms*—the most common initial signs and symptoms are growth or swelling, soreness and ulceration (**Fig. 16-9**).

Figs 16-7A and B: Carcinoma of buccal vestibule which also involve buccal mucosa (Courtesy Dr Suwas Darvekar).

Fig. 16-8: Carcinoma of buccal mucosa showing ulceration and white surface in the lesion (Courtesy Dr Parate).

Fig. 16-9: Carcinoma labial sulcus showing extensive lesion and ulceration.

- *Extent*—advanced lesion may be ulcerative-infiltrative type, showing exophytic growth.
- *Lymph nodes*—lymph node involvement may occur, which may be unilateral or bilateral (**Fig. 16-10**).

Fig. 16-10: Carcinoma of labial sulcus showing exophytic growth (Courtesy Dr Suwas Darvekar).

Carcinoma of palate

- *Cause*—it is common in area where reverse smoking is practiced.
- *Sex*—it is seen more commonly in females as compared to men, in case of reverse smoking.
- *Appearance*—palatal cancer usually manifests as a poorly defined ulcerated painful lesion on one side of the midline (**Figs 16-11A and B**).
- *Base and surface*—most of the lesions are exophytic and with broad base and nodular surface.

Figs 16-11A and B: Carcinoma of palate showing extensive lesion and ulceration (Courtesy Dr Suwas Darvekar).

- *Extent*—it frequently crosses the midline and may extend laterally to include tonsillar pillars or even the uvula. The tumor of hard palate may invade the bone or occasionally the nasal cavity. While infiltrating, lesions of the soft palate may extend into the nasopharynx.

Carcinoma of oropharynx

- *Site*—carcinoma of soft palate and oropharyngeal mucosa can occur.
- *Symptoms*—dysphagia, i.e. difficulty in swallowing is the most common complaint. Patient may complain of pain which is dull and sharp and is referred to ear.
- *Appearance*—it is same as that of other carcinoma.
- *Size*—size of the tumor is always greater than other carcinoma of the oral cavity.

Other specific carcinomas of gingiva, tongue, lip and maxillary sinus are described in their respective chapters.

Radiographic Features

- *Site*—it may be found along the entire border of the tumor or may be restricted to a relative small area. Irregular spicule of bone may be left behind.

- *Appearance*—there is roughly semicircular or saucer shaped erosion into the bone surface (Fig. 16-12).

Fig. 16-12: Saucer shaped erosion of mandible in lower left posterior region.

- *Margins*—there are ragged ill-defined borders that illustrate the varying uneven osteolytic invasion (Fig. 16-13). Rarely, the border may appear smooth without cortex indicating underlining erosion rather than invasion.

Fig. 16-13: Ill-defined margin seen in case of malignancy of maxillary posterior region (Courtesy Dr Parate).

- *Finger-like extension*—if the bone involvement is extensive then periphery appears to have finger-like extensions preceding a zone of impressive osseous destruction (Fig. 16-14).
- *Infiltration of bone*—little 'bays' of bone destruction extend into the bone, leaving irregular promontories of variable length and width extending into the main area of bone destruction. Margins of 'bays' are irregular and jagged. These produce a finger-like projection and this appearance is described as infiltration of the bone.
- *Pathological fracture*—sometimes when it involves the lower border of mandible, there may be so much bone loss where pathological fracture occurs (Figs 16-15 and 16).

Fig. 16-14: Finger-like extension seen in mandible in squamous cell carcinoma.

Fig. 16-15: Carcinoma involving mandible with pathological fracture on right side.

Fig. 16-16: Squamous cell carcinoma in parotid region with fracture.

- *Soft tissue mass*—a soft tissue mass is often present with carcinoma of jaw and this may be seen as faintly increased density in the radiograph (Fig. 16-17), standing above the general level of the bone.
- *Effect on surrounding tissues*—tumors may grow along the inferior neurovascular canal and through the mental foramen, resulting in an increase in the width and

Fig. 16-17: OPG showing soft tissue shadow which is seen as faintly increased density (Courtesy Dr Parate).

eventually the loss of cortical boundaries. Destruction of floor of nose, maxillary sinus and buccal or lingual mandibular plate may occur. The inferior border of mandible may be thinned or destroyed.

- *Effect on teeth*—there is widening of the periodontal ligament space with loss of adjacent lamina dura. Teeth appear to float in a mass of radiolucent soft tissue deprived of any bony support (**Fig. 16-18**). In extensive tumor soft tissue mass may grow into the teeth and teeth appear to be grossly displaced from its normal position.

Fig. 16-18: 'Floating teeth appearance' seen in maxillary anterior region.

- *Carcinoma of floor of mouth and buccal sulcus*—they cause bone destruction from sides of bone. In some cases, there is radiolucent area which contains small islands of slightly greater density. These areas represent finger-like projection of unaffected bone situated between the bay-like areas of infiltration and bone destruction, with the rays passing through the length of finger-like processes.

Diagnosis

- *Clinical diagnosis*—ulcerative growth with indurated base, rolled margin goes in favors of squamous cell carcinoma.
- *Radiological diagnosis*—ill defined radiolucency with infiltrative margin may diagnose this condition.
- *Laboratory diagnosis*—in this, there is increased number of mitotic figures, hyperchromatism with prominent and multiple nucleoli and increased nucleocytoplasmic ratio. There is also pleomorphism of cells, keratinization, and keratin pearls deep to epithelial surface and loss of intercellular bridges. Histopathologically, it can be well differentiated, moderately differentiated and poorly differentiated.

Differential Diagnosis

Clinical

- *Ulcerated benign tumor*—ulcer should heal in one to two weeks after removal of mechanical noxious agent.
- *Basal cell carcinoma*—a history of slower development and more common due to exposure to sunlight.
- *Ulceration due to systemic diseases*—usually multiple, generalized poor condition and is usually painful.
- *Primary syphilitic lesion*—causative agent is known, no pain, indurated ulcer usually reddish brown with copper color halo.
- *Necrotizing sialometaplasia*—rare inflammatory lesion of smaller salivary glands, particularly in the posterior hard palate, ulcers are usually painful with no raised borders, no hardening and characteristic histology.
- *Peripheral metastatic tumor*—low frequency.
- *Malignant salivary gland tumor*—common on posterior hard palate, common in women and maintain their dome-shape appearance.
- *Verrucous carcinoma*—slow growing and is associated with prolonged use of tobacco, surface is papillomatous and white due to retention of keratin.
- *Pyogenic granuloma*—moderately soft to palpation and bleed easily.

Radiological

- *Osteomyelitis*—it usually produces some periosteal reaction whereas squamous cell carcinoma does not.
- *Osteoradionecrosis*—history of radiation therapy and prior malignancy.
- *Periodontitis*—the margins of periodontitis are smooth and well defined as compared to carcinoma. Periodontitis is usually generalized and if it is localized, there is specific cause for it.
- *Papillon Lèfevre syndrome*—it produces symptoms of infection and shows areas of sequestration.

Management

Management is discussed in detail at the end of this chapter:

- *Removal of cause*—removal of any local irritants i.e. the (5-S) smoking, spices, spirit, sepsis and syphilis.
- *Excisional biopsy*—excisional biopsy, if lesions are small.
- *Surgery*—cryosurgery, laser surgery and radical surgery.
- *Radiation*—radiation can be given in squamous cell carcinoma.
- *Chemotherapy*—chemotherapy is usually given in patient who cannot undergo surgical or radiation therapy.

Metastatic Carcinoma

It is also called as 'secondary carcinoma'. It is the most common malignant tumor in the skeleton. This tumor is transported to an area distant from its origin and establishes a new foothold and are said to have metastasized. Although the metastatic carcinoma of jaw is uncommon, its recognition is important because the jaw tumors may be the first indication that the patient has a malignant disease. Oral diagnostician can make an invaluable contribution of pathologic process of bone. Most common sites of origin are breast, lung, kidney, thyroid, prostate and colon.

Clinical Features

- *Age*—it is found in patients between 40 and 60 years of age and there may be history of primary tumor.
- *Site*—mandible is involved much more frequently than maxilla (**Fig. 16-19**), especially in the region near premolars and molars as tumor metastasizes to those bones which are rich in hemopoietic marrow. It is said that blood flow rate is decreased in areas of

Fig. 16-19: Extraoral swelling seen in metastatic carcinoma in mandibular region.

hemopoietic marrow and this predisposes tumor emboli to settle and grow in these areas. This hypothesis is consistent with jaw metastases as hemopoietic marrow is most routinely found at this site. The other sites involved are maxillary sinus, anterior hard palate and mandibular condyle.

- *Symptoms*—there may be pain, swelling, and paresthesia.
- *Numb chin syndrome*—it occurs when metastatic carcinoma involve inferior alveolar nerve. There is unexplained loss of sensation in lower lip and chin.
- *Appearance*—early lesion is nodule or dome shaped with smooth surface and due to trauma, may get ulcerated.
- *Teeth mobility*—teeth in this region may become loose or exfoliate and root resorption may occur. There is loss of bony support with periodontitis.
- *Swelling*—on occasion, tumor may breach the outer cortical palate of jaws and extend into surrounding soft tissue or presents as an intraoral mass.
- *Unhealed socket*—metastatic tumors are diagnosed only when the sockets of extracted teeth do not heal because of periodontal disease.
- *Loss of function of muscle*—if invasion occurs in muscle then their functions are impaired.
- *Pathological fracture*—there may be pathological fracture of the jaw or hemorrhage from the tumor site.

Radiographic Features

Osteolytic type

- *Radiodensity*—ill-defined radiolucent destructive lesion may be single or multiple and vary in size.
- *Site*—it is seen in mandible (**Fig. 16-20**) and are bilateral in occurrence. The lesion may be located in the periodontal ligament space.
- *Appearance*—an appearance that is highly suggestive of metastatic carcinoma is the combination of an area of bone destruction having very irregular margins with islands of bone within radiolucent areas.
- *Moth eaten appearance*—the other appearance of the lytic type of metastasis in the jaw is one that has considerable

Fig. 16-20: Osteolytic variety of metastatic carcinoma showing radiolucency in mandibular right posterior region (Courtesy Dr Ashok L).

resemblance to some manifestation of osteomyelitis. There is an area of bone destruction or there may be two or more separated areas.

- *Infiltrative margin*—irregular bone destruction takes place from each separated site of origin and there is evidence of infiltrative margins in the areas of destruction.
- *Punched out radiolucency*—there may be multiple punched out radiolucency when several nests of tumor cells are located close to each other.
- *Margins*—it may be well demarcated but without cortication or encapsulation. They may have ill defined invasive margins.
- *Periodontal ligament widening*—in some metastatic tumor, there is widening of periodontal ligament.
- *Effect on surrounding structures*—if it occurs in alveolar bone, there is loss of lamina dura leading to mobility or loss of teeth. If the tumor has seeded in the papilla of a developing tooth, the cortices of crypts may be totally or partially destroyed. The cortical structures such as the neurovascular canal, sinus and nasal fossa are destroyed.

Osteoblastic type (Fig. 16-21)

- In some cases, osteoblastic variety of metastatic carcinoma can occur which depend upon whether the metastasized tumor cell produce significant level of acid or alkaline phosphatase.
- *Salt and pepper appearance*—irregular ‘salt and pepper appearance’ can be seen in some cases. Metastatic tumor widely disseminate in multiple nests in the bone. These nests appear as small radiolucent (pepper) areas. They induce sclerosis about themselves and thus separate the overall image with small radiopaque foci (salt).

Fig. 16-21: Osteoblastic variety of metastatic carcinoma
(Courtesy Dr Ashok L).

Diagnosis

- *Clinical diagnosis*—unexplained mobility of teeth, unhealed socket with numb chin syndrome may suspect metastatic carcinoma.
- *Radiological diagnosis*—salt and pepper appearance are seen in osteoblastic variety and ill defined radiolucency are seen in osteolytic variety.
- *Laboratory diagnosis*—biopsy features are similar to squamous cell carcinoma.

Differential Diagnosis

- *Exophytic squamous cell carcinoma*—there is history of primary tumor. Clinically squamous cell carcinoma is well distinguishable.
- *Multiple myeloma*—the borders of multiple myeloma are better circumscribed than metastatic tumor.
- *Periapical inflammatory lesion*—if the metastatic tumor is situated in the periodontal ligament space then it may be confused with metastatic tumor. But in case of inflammatory lesion, periodontal ligament space widening is more centered around the apex of the teeth and in metastatic tumor there is irregular widening.
- *Malignant salivary gland tumor*—it is not so common in mandible.

Management

- *Combination therapy*—It can be treated by chemotherapy, radiation therapy, surgery, immunotherapy and hormone therapy. Prognosis is poor and death occurs within a short time.

Basal Cell Carcinoma

It is also called as ‘*basal cell epithelioma*’ or ‘*Rodent ulcer*’. It arises from basal layer of epidermis or from the hair follicle.

Etiology

- *Prolonged exposure to sunlight*—the specific factor in sunlight responsible for skin carcinogenesis appears to be an ultraviolet radiation.
- *Others factors*—other factors are also responsible like burn scars and ionizing radiation. General atrophy associated with aging process; at least, predispose to develop the skin cancer.

Clinical Types

- *Nodular (noduloulcerative) basal cell carcinoma*—clinically, it appears as nodular lesion with central depression.
- *Pigmented basal cell carcinoma*—tumor is colonized by benign melanocytes.

- *Sclerosing (morpheaform) basal cell carcinoma*—it mimics scar tissue.
- *Superficial basal cell carcinoma*—occurs on skin of the trunk.
- *Nevoid basal cell carcinoma*—basal cell carcinoma is associated with syndrome.

Histological Types

- *Adenoid basal cell carcinoma*—it represent neoplasm which mimics glandular formation.
- *Cystic basal cell carcinoma*—presence of many cysts in the lesion.
- *Keratotic basal cell carcinoma*—formation of parakeratotic cells and horn cysts and attempted formation of hair structures to the trichoepithelioma.
- *Solid or primordial basal cell carcinoma*—cells have little tendency to differentiate.

Clinical Features

- *Age and sex distribution*—it is seen in middle aged or elderly person usually in 4th decade of life. It is much more common in men than women because men are exposed to the environmental elements more than women.
- *Site*—it develops most frequently on exposed surface of skin, middle-thirds of face and the scalp. There is also involvement of lip. The upper lip is involved more commonly than the lower lip.
- *Race*—blond people with fair complexion who have spent much of their lives outdoors are often victim of these lesions.
- *Appearance*—it begins as a small, slightly elevated papule which ulcerates, heals over and then breaks down again to form crusted ulcer.
- *Margins*—it develops a smooth, rolled border representing tumor cells spreading laterally beneath the skin (Fig. 16-22).

Fig. 16-22: Rolled margin seen in basal cell carcinoma showing spread in the skin.

- *Rodent ulcer*—untreated lesion continues to enlarge and infiltrate the adjacent and deeper tissues and it may even erode deeply into the cartilage or bone. Due to its invading and destructive infiltration into adjoining tissues, it gradually increases in size and accounts for its synonym 'rodent ulcer' (Fig. 16-23).

Fig. 16-23: Destruction of skin occur in basal cell carcinoma signifying its name as 'rodent ulcer'.

- *Intraoral lesion*—it is never seen in oral cavity unless it arrives there by invasion and infiltration from a skin surface.
- *Nodular (noduloulcerative) basal cell carcinoma*—it is firm painless papules with central depression and has umbilicated appearance. When the lesion is pressed, characteristic pearly opalescent quality is seen.
- *Pigmented basal cell carcinoma*—the melanin production imparts a tan, brown, black color of the lesion. In some cases, it is even bluish in color.
- *Sclerosing (morpheaform) basal cell carcinoma*—in this, overlying skin appear pale, atrophic and lesion is firm on palpation. Margins are poorly demarcated.
- *Superficial basal cell carcinoma*—it is multiple, well demarcated lesions seen on skin. It is also erythematous scaly patches some time mistaken as psoriasis.
- *Lymph node involvement*—occasionally, it may metastasize to lymph nodes.

Diagnosis

- *Clinical diagnosis*—rolled margin with ulcerative lesion on the skin of the face with destruction of skin, suggestive of basal cell carcinoma.
- *Laboratory diagnosis*—biopsy will show cell nests which are composed of a layer of cells, usually well polarized, that are strongly suggestive of the basal cell layer of skin.

Management

- *Simple surgical excision*—it is indicated in small lesion which is less than 1 cm in diameter. Surgery can be performed by laser ablation, electrodesiccation and curettage.
- *Radical surgical excision and radiotherapy*—it is given in extensive and aggressive lesion.
- *Mohs micrographic surgery*—it is indicated in sclerosing lesion. It is used for frozen section evaluation if any tissue is left behind. If tissue remains then surgeon remove the tissue immediately and process is repeat until patient is free of disease.

Transitional Cell Carcinoma

These lesions arise chiefly from the tonsil, base of the tongue and nasopharynx due to presence of stratified epithelium in this area. It is extremely malignant, running a rapid clinical course, metastasizing widely and causing very early death.

Clinical Features

- *Age and sex distribution*—mean age of occurrence is 44 years.
- *Symptoms*—there may be sore throat, nasal obstruction, defective hearing or ear pain, headache, dysphagia, epistaxis and ocular symptoms.
- *Primary lesion*—the primary lesions are very small often completely hidden, usually slightly elevated (**Fig. 16-24**). In some cases, primary lesion is ulcerated with granular eroded surface.
- *Advanced lesion*—as the tumor is advanced, its size is increased rapidly and base of tumor appear indurated. In some instances, it appears as an exophytic or fungating growth.
- *Lymph nodes*—swelling of regional lymph node is the most common occurrence.

Fig. 16-24: Carcinoma seen in tonsillar area occur due to tonsillar cell malignancy.

Diagnosis

- *Clinical diagnosis*—any ulcerative growth in the region of tonsil, nasopharynx and base of tongue will suspect transitional cell carcinoma.
- *Laboratory diagnosis*—biopsy shows cells growing in solid sheets or in cords and nests. The individual cell is moderately large, round or polyhedral and exhibit a lightly basophilic cytoplasm and indistinct cell outlines. There are large nuclei with presence of mitotic activity.

Management

- *Radiation*—X-ray radiation is the most commonly accepted treatment.

Malignant Melanoma

It is also called as '*melanosarcoma*'. It is a neoplasm of epidermal melanocytes. It is one of the biologically unpredictable and deadly of all human neoplasms.

Etiology

- *Sunlight*—it is very important etiological factor in cutaneous melanoma. Acute sun damage causing melanoma is more as compared to chronic sun damage.
- *Genetic*—chances of malignant melanoma increases in a person whose relative has got the history of cancer.
- *Other factors*—other factors like fair complexion, history of blistering sunburns, indoor occupation with outdoor recreation habits and history of dysplastic or congenital nevus may be contributed for the development of malignant melanoma.

Types

- *Superficial spreading melanoma*—It is the most common cutaneous melanoma.
- *Nodular melanoma*—it is a form of cutaneous melanoma and occurs in head and neck area.
- *Lentigo maligna melanoma*—it develops from precursor lesion called lentigo maligna.
- *Acral lentiginous melanoma*—it is the most common form of melanoma in black. It is most common in oral cavity.

Growth Pattern

- *Radial growth phase*—the radial growth phase may last for several months to several years. In this phase, malignant melanocytes spread horizontally through basal layer of epidermis.
- *Vertical growth phase*—the vertical growth phase is characterized by increase in size, change in color, nodularity and at times, ulceration. In this phase, malignant cells invade underlying connective tissue.

Clinical Features

Superficial spreading melanoma

- **Age**—The majority of cases are diagnosed in the 5th to 7th decade of life. It is more common in males as compared to females in the ratio of 2:1.
- **Site**—the lesion presents as a tan brown, black or admixed lesion on sun exposed skin, especially in blacks. It also occurs on skin of face (**Fig. 16-25**), head and neck, chest, abdomen and extremities.

Fig. 16-25: Malignant melanoma seen on face of patient showing ulceration.

- **Appearance**—it begins as pigmented macule in superficial radial growth pattern, restricted mostly to epithelium and junction. In advanced cases, melanoma present as an ulcerated, fungating growth which is associated with bleeding.
- **Amelanotic melanoma**—Some lesions are devoid of pigmentation which is called as amelanotic melanoma.

Nodular melanoma

- **Site**—they have a predilection for occurrence on head and neck of men.
- **Color**—color varies from mucosal pink through brown and blue to black.
- **Consistency**—it is firm on palpation.
- **Margins**—it has got erythematous borders which surround the tumor.
- **Extent**—there is rapid infiltration in nodular type of melanoma. It may be focal or diffuse.
- **Signs**—many times, it may ulcerate and hemorrhage may be seen. In later stages, it becomes more diffuse, nodular and tumefactive with foci of hypo- and hyperpigmentation. It presents as a sharply delineated nodule with some degree of pigmentation.

Lentigo maligna melanoma

- **Sex**—it occurs more often in women than in men.
- **Site**—it has got predilection for exposed parts.

- **Margins**—it is pigmented macule with ill defined margins.
- **Appearance**—it occurs characteristically as a macular lesion of the malar area.
- **Progress**—it grows slowly in radial phase, with around the central axis and in a superficial manner.
- **Extent**—as the disease advances, invasion and metastasis are frequent.

Acral lentiginous melanoma

- **Synonym**—it is also called as mucosal lentiginous melanoma.
- **Site**—it develops on palms of hands, soles of the feet, sublingual area and mucous membrane.
- **Appearance**—it develops as dark pigmented irregularly margined macule.

Oral Manifestations

- **Age and sex**—it is an uncommon neoplasm of the oral mucosa and it is more common in men than in women with the overall age of occurrence being 55 years, with most cases occurring between 40 to 70 years.
- **Site**—it has got definite predilection for palate and maxillary gingiva/alveolar ridge followed by buccal mucosa, mandibular mucosa, tongue, lips and floor of mouth.
- **Preceding factors**—focal pigmentation preceding the development of actual neoplasm frequently occurs, several months to years before clinical symptoms appear.
- **Symptoms**—oral melanomas are generally painless. The lesion presents as a soft, darkish brown or black mass. It may have a nodular or a papillary surface.
- **Appearance**—the lesions usually appear as deeply pigmented areas, at times ulcerated and hemorrhagic (**Fig. 16-26**), which tend to increase progressively in size.

Fig. 16-26: Intraoral malignant melanoma presented as darkly pigmented brownish lesion with ulceration.

- **Signs**—the tumor causes extensive destruction of the underlying bone; loosening of teeth may be a concomitant clinical finding. There may be ulcerations and bleeding of the oral mucosa.
- **Base and margins**—there is minimum induration and no rolled margins are seen.

Radiographic Features

- **Radiodensity**—some melanomas in the jaws may present radiographic picture which is indistinguishable from osteomyelitis. Sometimes, small radiolucency with irregular border may be seen (**Fig. 16-27**).

Fig. 16-27: Radiolucency seen in upper region which is irregular in shape in case of malignant melanoma (Courtesy Dr Parate).

Diagnosis

- **Clinical diagnosis**—darkly pigmented lesion with ulceration will give clue to the diagnosis.
- **Radiological diagnosis**—not specific.
- **Laboratory diagnosis**—in superficial spreading melanoma melanocytes are arranged in “pagetoid manner”. In case of nodular melanoma, there are large, epithelioid melanocytes within the connective tissue. Small ovoid and spindle shaped cells may be present. Lentigo melanoma is characterized by increased number of atypical melanocytes with the basal epithelial layer.

Histological Grading of Malignant Melanoma

- It depends upon the depth upto which malignant cells have invaded or infiltrated into the connective tissue.
- **Grade I**—malignant cells are confined within the epithelium.

- **Grade II**—malignant cells have invaded into the papillary dermis.
- **Grade III**—malignant cells have invaded into the level of reticular dermis.
- **Grade IV**—malignant cells have completely invaded the reticular dermis.
- **Grade V**—malignant cells have extended into the subcutaneous fat.

Management

- **Surgical excision**—it is treated by surgical excision. Surgical removal of regional lymph nodes should also be carried out.
- **Other therapy**—other therapy like irradiation, immunotherapy and chemotherapy or, by combination of these methods can also be tried. Survival rate is very poor and is worse with metastasis.

Verrucous Carcinoma

It is a slow growing low-grade carcinoma. It is also called as ‘Snuff dipper cancer’, ‘Ackerman’s tumor’. It is reported by Ackerman in 1948 as spit tobacco associated malignancy.

Etiology

- **Tobacco**—tobacco chewers have high percentage of these cases. It occurs usually in a person habitual to hold the quid in the buccal sulcus (**Fig. 16-28**).

Fig. 16-28: Verrucous carcinoma seen in buccal mucosal area where patient is used to keep tobacco (Courtesy Dr Bhaskar Patle).

Clinical Features

- **Age and sex**—it is generally seen in elder population with mean age of occurrences of 60 to 70 years. Men are affected more as compared to women.

- **Common sites**—they are larynx, external auditory meatus, lacrimal duct, skin, scrotum, penis, vulva, vagina, uterine cervix, perineum, leg and odontogenic cyst linings. In the oral cavity, it occurs on buccal mucosa (Fig. 16-28) and gingiva or alveolar ridge.
- **Symptoms**—pain and difficulty in mastication are common complaints.
- **Appearance**—they appear papillary in nature with pebbly surface which is sometimes covered by a white leukoplakic film (Fig. 16-29). They have rugae-like folds with deep cleft between them (Fig. 16-30). In some cases, there may be warty fungating mass.
- **Base**—large broad lesion with minimum to extensive elevation above the surface of mucosa.
- **Margins**—margins are well defined and show rim of slightly elevated normal mucosa (Fig. 16-31).
- **Color**—color is usually white but it can be erythematous or pink.

Fig. 16-29: Pebbly surface of verrucous carcinoma surrounded by leukoplakic film (Courtesy Dr Parate).

Fig. 16-30: Warty growth with cleft in between in verrucous carcinoma (Courtesy Dr Chole).

Fig. 16-31: Well defined and slightly elevated margins in verrucous carcinoma.

- **Lymph nodes**—regional lymph nodes are often tender and enlarged simulating metastatic tumor, but the node involvement is usually inflammatory.
- **Extent**—lesion on the mandibular mucosa grows into overlying soft tissue and rapidly becomes fixed to the periosteum, gradually invading and destroying the mandible.
- **Progress**—oral lesion is slow growing, chiefly exophytic and only superficially invasive, at least until late in the course of the disease and has a low metastatic potential.
- **Prognosis**—prognosis in verrucous carcinoma is very good because of absence or late appearance of metastases.

Diagnosis

- **Clinical diagnosis**—verrucous papillary surface with cleft in between with history of tobacco keeping at location where lesion is found.
- **Laboratory diagnosis**—in biopsy, there is marked epithelial proliferation, parakeratin plugging and pushing margin.

Differential Diagnosis

- **Verrucous hyperplasia**—verrucous hyperplasia is a proliferative epithelial lesion with epithelial hyperplastic fold extending above the margins of surrounding mucosa whereas in verrucous carcinoma, folds invade down into connective tissue and hence are below the surrounding normal mucosal margin.
- **Chronic hyperplastic candidiasis**—in it, epithelial hyperplasia is not so extensive as in verrucous carcinoma and the cleft-like spaces often seen between the heaped up masses of carcinomatous epithelium.
- **Well differentiated squamous cell carcinoma**—lymph nodes metastasis is extensive. Histopathological investigation should be carried out to confirm the diagnosis.

Management

- *Surgical excision*—excision must be sufficiently radical to remove the entire lesion.

Spindle Cell Carcinoma

It is also called as 'Lane tumor', 'polypoid squamous cell carcinoma' or 'carcinosarcoma'. It occurs chiefly in respiratory and alimentary tracts. It is a variant of squamous cell carcinoma. There is proliferation of spindle cells believed to be arising from the surface epithelium. Many cases of spindle cell carcinoma develop as a recurrence after radiotherapy to the squamous cell carcinoma. This phenomenon is called as 'dedifferentiation'.

Clinical Features

- *Sex and age distribution*—it is more common in male with mean age of occurrence of 57 years.
- *Common site*—lower lip, tongue and alveolar ridge or gingiva with remainder scattered at other site.
- *Symptoms*—there is swelling, pain and presence of a non-healing ulcer.
- *Appearance*—the initial lesions appear either with a polypoid, exophytic or endophytic configuration. The lesion is fleshy.
- *Progress*—it grows rapidly and diagnose at later stage.

Diagnosis

- *Clinical diagnosis*—rapidly growing polypoid exophytic mass can yield in the clinical diagnosis of the lesion.
- *Laboratory diagnosis*—biopsy will show proliferation and 'dropping off' of basal cell to spindle cell.

Management

- *Radical surgery*—surgical removal of tumor with or without radical neck dissection is usually recommended.
- *Radiotherapy*—radiation therapy is also used in some cases.

Adenoid Squamous Cell Carcinoma

It is also called as 'adenoacanthoma'. It arises from pilosebaceous structures or senile keratosis with acantholysis.

Clinical Features

- *Sex and age distribution*—females are affected more with age ranging from 20 to 50 years and older.
- *Common site*—it more commonly occurs on lip and also in head and neck region. The lower lip is affected more commonly than upper lip and common on the vermillion border of lip.

- *Appearance*—it appears as simply elevated nodules (Fig. 16-32) that may be slow crusting, scaling. Usually, there is no surface ulceration.
- *Margins*—sometimes, there are elevated or rolled borders of the lesion.
- *Prognosis*—prognosis is good and metastasis is rare.

Fig. 16-32: Nodular elevated lesion seen on lower lip suggestive of adenoid squamous cell carcinoma (Courtesy Dr Suwas Darvekar).

Diagnosis

- *Clinical diagnosis*—lesion on lower lip with nodular surface and scaling will yield in diagnosis.
- *Laboratory diagnosis*—in biopsy, epithelium show the characteristic solid and tubular ductal structures which are lined by a layer of cuboidal cells and often contain or enclose acantholytic or dyskeratotic cells.

Management

- *Surgical excision*—it is treated by surgical excision.

Nasopharyngeal Carcinoma

It is tumor which arises from lining epithelium of lymphoid tissue rich nasopharynx. It can be caused by environmental factors, infection with Epstein-Barr virus, vitamin C deficient diet, and consumption of salt fish which contains carcinogen N-nitrosamines.

Clinical Features

- *Age and sex distribution*—it is common in older age group and more common in men as compare to women.
- *Onset*—the initial lesion is small and difficult to detect.
- *Symptoms*—patient may notice serous otitis media, otalgia and hearing loss from obstruction of eustachian tube. Other symptoms noticed are nasal obstruction and pharyngeal pain. If the tumor involves brain, it may cause neurological symptoms.

- *Signs*—first sign is, firm to hard cervical lymph nodes which may be enlarged in size.

Diagnosis

- *Clinical diagnosis*—ear symptoms with pharyngeal pain with cervical lymphadenopathy may give clue to the diagnosis.
- *Laboratory diagnosis*—biopsy may show features suggestive of squamous cell carcinoma, differentiate non-keratinizing carcinoma, and undifferentiated non-keratinizing carcinoma.

Management

- *Radiotherapy*—as the tumor is inaccessible, it is more frequently treated with radiotherapy.

Multicentric Oral Carcinoma

Multiple primary tumors occur in about 10% of patients with oral cancer. It is usually seen in alcoholics and heavy smokers. The reason for this is that the whole mucosa is often in an abnormal state for long periods, prior to the development of oral cancer. The commonest finding is that there is area of atrophy, either adjacent to a carcinoma or randomly distributed.

Tumors of Fibrous Connective Tissues

Fibrosarcoma

It is malignant neoplasm composed of malignant fibroblast that produces collagen and elastin. It arises in the periosteal tissue. It may arise secondarily in tissues that have received therapeutic levels of radiation. It is one of the most common soft tissue sarcoma.

Clinical Features

- *Age and sex*—onset at any age with mean age of occurrence of 50 years with male predominance.
- *Common sites*—it is commonly associated with cheek, maxillary sinus, pharynx, palate, lip and periosteum of maxilla and mandible. Mandible is more commonly affected than maxilla.
- *Symptoms*—It produces fleshy bulky mass of tissue. There may be pain and loosening of the teeth. Involvement of TMJ and para-mandibular musculature are producing trismus. Sensory neural abnormalities may occur if it involves peripheral nerves.
- *Signs*—initially they resemble benign fibrous outgrowth, but they grow rapidly to produce large tumor. Large tumors are prone to ulceration and hemorrhage (Figs

16-33A and B). Secondary infections are seen in some cases. In some cases, pathological fracture may occur.

- *Maxillary lesions*—maxillary lesions are quite destructive and invade the antrum.
- *Extent*—they tend to penetrate the cortex and spread along the periosteum.

Figs 16-33A and B: Extraoral and intraoral view of fibrosarcoma showing extensive ulcerative growth.

Radiographic Features

- *Radiodensity*—destructive lesion may stimulate the osteolytic form of osteosarcoma.
- *Margins*—they are poorly demarcated, non-corticated and lack of any resemblance of capsule.
- *Extent*—they tend to elongate through marrow space.
- *Appearance*—if soft tissue lesions occur adjacent to bone, they cause a saucer-like depression (Fig. 16-34) in the underlying bone or invade it as seen in a squamous cell carcinoma.
- *Teeth*—teeth are displaced and loose their supporting bone so that they appear to be floating in space. Lamina dura and follicular cortices are obliterated. In some cases, periodontal space widening may occur.

- *Maxillary sinus*—inferior border of maxillary sinus, posterior wall of maxilla, nasal floor, inferior border of mandible and neurovascular canal are lost.
- *Pressure effect*—if it is developed from the periosteum, it may cause a smooth pressure resorption of underlying bone.

Fig. 16-34: Saucer shaped erosion seen in premolar area in fibrosarcoma.

Diagnosis

- *Clinical diagnosis*—fleshy mass with ulceration in the soft tissue area will suspect fibrosarcoma.
- *Radiological diagnosis*—saucer shaped erosion of bone is present.
- *Laboratory diagnosis*—proliferation of fibroblasts and formation of collagen and reticular fibers. Mitotic figures are prominent in small group of poorly differentiated tumors.

Differential Diagnosis

- *Metastatic carcinoma*—there is history of primary tumor and it usually does not cause enlargement of jaw.
- *Osteosarcoma*—there is typical sunray appearance.
- *Liposarcoma*—it is very rare in jaws.
- *Neurogenic sarcoma*—it is difficult to differentiate.

Management

- *Radical surgical excision*—it is most commonly used treatment modality.

Malignant Fibrous Histiocytoma

It is also called as '*malignant fibroxanthoma*'. Neoplasm that exhibits both histiocytic and fibrocytic features are referred to as histiocytomas. It is one of the most common soft tissue sarcoma of soft tissues of body.

Types (Histological)

- Giant cell
- Inflammatory
- Myxoid
- Storiform
- Pleomorphic
- Angiomatoid

Clinical Features

- *Age and sex*—there is slight male predilection and malignant variety is common in adults.
- *Site*—in the head and neck area, more commonly encountered in the paranasal sinuses or centrally, within the jaw.
- *Appearance*—occasionally, it arises in the oral cavity and in the lateral neck, it appears as indurated swelling.
- *Metastasis*—in nearly 1/4th of cases have been reported.

Radiological Features

- *Appearance*—it produces unilocular or multilocular radiolucent areas.
- *Margins*—lesion has got ill-defined borders.

Diagnosis

- *Clinical diagnosis*—not specific.
- *Radiological diagnosis*—not specific.
- *Laboratory diagnosis*—the spindle cells are arranged in fascicles with a pinwheel or storiform pattern. The deep seated tumors contain both epithelioid histiocytes and spindle shaped fibroblast. Both cell component display marked hyperchromatism, pleomorphism and atypical mitoses with many multinucleated cells exhibiting angulated cytoplasmic borders.

Management

- *Surgical excision*—it is treated by surgical excision or radiation with 5 year survival rate in 20 to 60% of cases.

Synovial Sarcoma

It usually arises from articular or para-articular sites, bursae or tendon sheath. Synovial sarcoma of head and neck are rare.

Clinical Features

- *Age and sex distribution*—it is predominately seen in young adults mean age being 19 years. It has got slight male predilection.
- *Sites*—intraoral sites are cheek, tongue, floor of mouth and soft palate.
- *Symptoms*—there is painless deep seated swelling which may produce difficulties in breathing or swallowing.

Diagnosis

- *Clinical diagnosis*—it is not specific.
- *Laboratory diagnosis*—it is characterized by biphasic cellular pattern of cleft-like or slit-like spaces lined by cuboidal epithelial-like cells. The space may contain PAS positive mucoid material. There may be fibrosarcoma like proliferation of cells, with associated collagen or reticulum.

Management

- *Radical resection*—early radical resection is the best method of treatment.
- *Adjunct radiotherapy*—it can also be given after radical resection.
- *Prognosis*—it has got poor prognosis as tumor often metastasized.

Tumors of Adipose Tissues

Liposarcoma

It is extremely uncommon malignant tumor of head and neck region.

Clinical Features

- *Age and sex*—it most frequently occurs in adults over the age of 40 years with predilection in males in ratio of 2:1.
- *Site*—the most common site is thigh, retroperitoneum and inguinal region. The most frequent oral region affected is cheek which is followed by tongue.
- *Symptoms*—pain and tenderness may be present in advanced cases of liposarcoma.
- *Appearance*—it has a slow, silent growth, submucosal or deep in location, producing firm, resilient lesions, sometimes lobulated.
- *Color*—color of lesion is normal or yellow in color.

Diagnosis

- *Clinical diagnosis*—soft, yellow color growth on the cheek may suspect liposarcoma.
- *Laboratory diagnosis*—histologically, it is classified into myxoid, round cell, adult and pleomorphic types. In general, it consists of fat cells and lipoblast in varying degrees of differentiation and anaplasia with variable stromal component.

Management

- *Surgical excision*—it is treated by surgical excision with or without radiation therapy.

Cartilage Tumors

Chondrosarcoma

It is also called as '*chondrogenic sarcoma*'. It develop from natural cartilage or a benign cartilaginous tumor. Most of them develop from cartilage located in bone either centrally in bone (medullary cavity) or peripherally, from the cartilage cup of an osteochondroma.

Types

- *Primary*—they directly arise from the cartilage.
- *Secondary*—it develops in a preexisting benign cartilaginous tumor.

Clinical Features

- *Age and sex*—develop during 3rd to 6th decades and male to female ratio is 2:1. Secondary chondrosarcoma occur at early age than the primary type of chondrosarcoma.
- *Site*—it is rare in jaws and may occur in maxilla or mandible. Often found in anterior alveolar process of maxilla and in mandible, it is found at angle and alveolar ridge of premolar-molar region.
- *Progress*—it is slow growing and less malignant.
- *Symptoms*—painless in early stages with facial asymmetry as first complain but as it enlarges, swelling becomes bony hard and painful. There may be headache.
- *Signs*—teeth adjacent to the lesion are resorbed, loosened and get exfoliated. In some cases, there may be hemorrhage from the neck of teeth. There may be sensory nerve deficit, proptosis and visual disturbances. If swelling erodes through the cortical plate, it tends to be tender, smoothly contoured firm mass due to presence of cartilage.
- *Surface of lesion*—mucosal covering appears normal in early stage (**Fig. 16-35**) but later, it ulcerates and develops necrotic surface, if chronically traumatized.
- *Temporomandibular joint involvement*—if it occurs in/or near the temporomandibular joint region (**Fig. 16-36**), trismus and abnormal joint function may result.
- *Metastasis*—metastatic spread by vascular channel. Malignant cells may erode through wall or venules and extend along inside the venules without adhering to vessels wall but still altered at their site of entry. Lung is common region of metastasis.

Radiographic Features

- *Radiodensity*—it may be sclerotic or mixed, if there is calcification of neoplastic tissue.
- *Margins*—lytic lesions with poorly defined borders.
- *Shape*—the lesion is round, ovoid or lobulated.

Fig. 16-35: Chondrosarcoma of palate showing displacement of teeth and normal appearing mucosa in early stage.

Fig. 16-36: Chondrosarcoma of condyle (Note the swelling in condylar region).

- *Flocculent or snow-like appearance*—it may be multi-loculated or develop as multiple radiolucency containing radiopaque foci. The center radiopaque structure has been described as 'flocculent', implying *snow-like* features.
- *Soap bubble appearance*—large lobules of cartilage may give a radiolucent soap bubble appearance.
- *Ground glass or granular appearance*—diffuse calcifications may be superimposed on a bony background that resembles granular or ground glass appearance.
- *Sunray appearance*—occasionally, peripheral periosteal new bone may be present perpendicular to the original

cortex, giving so called sunray appearances. Sometimes, ground glass appearance may be seen.

- *Speckled appearance*—careful examination of areas of flocculence may reveal a central radiolucent nidus which is probably cartilage, surrounded by calcification. The result is rounded or speckled areas of calcification.
- *Teeth*—there may be band-like widening of periodontal ligament space; resorption of root may occur.
- *Mandibular lesion*—in mandible, inferior border or alveolar process may be grossly expanded, while still maintaining its cortical covering.
- *Maxillary lesion*—maxillary lesion may push the walls of maxillary sinus or nasal fossa and impinge on the infratemporal fossa.
- *Condylar lesion*—lesion on the condyle cause it's expansion and remodeling of the corresponding articular fossa and eminence (**Fig. 16-37**). If the lesion occurs in the articular disc region, a widened joint space may be present with corresponding remodeling of condylar neck.
- *3D CT features*—it may demonstrate lesion very clearly (**Fig. 16-38**).

Fig. 16-37: Destruction of condyle on left side of patient in chondrosarcoma of condyle.

Fig. 16-38: Chondrosarcoma of condyle a 3D CT picture (Courtesy Dr Iswar).

Diagnosis

- *Clinical diagnosis*—this can be included in differential diagnosis of swelling of condylar region.
- *Radiological features*—flocculent appearance, sunray appearance and in some cases, ground glass appearance is seen.
- *Laboratory diagnosis*—biopsy shows hyaline cartilage, increased number of cells with plump nuclei. Histopathologically, it can be grade I, Grade II or Grade III chondrosarcoma.

Differential Diagnosis

- *Osteosarcoma*—the typical calcification of chondrosarcoma is not present in osteosarcoma.
- *Fibrous dysplasia*—the periphery of fibrous dysplasia is better defined. In fibrous dysplasia there is thinning of periodontal ligament space and in chondrosarcoma, there is usually a widening of periodontal ligament space.

Management

- *Surgery*—it is the only treatment of choice and there is 5 years survival rate. Complete resection should always be done to avoid recurrence.

Mesenchymal Chondrosarcoma

This is aggressive form of chondrosarcoma showing biphasic histopathological pattern. It contains mesenchymal cells. It tends to metastasize to unusual locations and that too after long period of time. Most of the tumors arise in bone but an appreciable number occur in soft tissues.

Clinical Features

- *Age*—it is seen in younger age group than usual type of chondrosarcoma. It is usually seen between the ages of 10 and 30 years.
- *Site*—it is most commonly seen in maxilla, skull bone, mandible and ribs. It also occurs in tubular bones and pelvis.
- *Symptoms*—there may be pain due to compression of nerve. In some cases, there may be swelling.
- *Sign*—pathological fracture may also occur.

Radiological Features

- They are same as chondrosarcoma

Diagnosis

- *Clinical diagnosis*—younger age group with complaints of pain and swelling in maxillary area.

- *Radiological features*—same as that of chondrosarcoma.
- *Laboratory diagnosis*—the mesenchymal chondrosarcoma consist of sheets of small, round or ovoid, undifferentiated cells interspersed by small islands of well differentiated cartilage which often show calcifications and metaplastic bone formation.

Management

- *Surgery*—surgical excision with wide margin is the treatment of choice. The prognosis is poor and most patients may die due to metastasis.

Bone Tumors

Osteosarcoma

It is also called as 'osteogenic sarcoma'. It is the most common malignant tumor originated within the bone. It is derived from osteoblasts in which tumor cells contain high level of alkaline phosphatase.

Etiology

- *After radiation therapy*—there are increased incidences of osteosarcoma in bone that has been irradiated.
- *Traumatic irritation*—it may be causative factor for osteosarcoma.
- *Fibro-osseous diseases*—osteogenic sarcoma may be seen in fibrous dysplasia and Paget's disease.
- *Others*—other causes which can cause osteosarcoma are genetic mutation and some viral causes.

Clinical Features

- *Age and sex*—mean age of occurrence in the jaws is 33 years and it is more common in males.
- *Site*—it is more common in long bones like femur and tibia and in jaw bone.
- *Progress*—it grows rapidly with a doubling time of 32 days and shows recurrence and early metastasis via bloodstream to lungs (Fig. 16-39).
- *Signs*—there is exophthalmos, blindness, nasal obstruction and epistaxis.

Oral Manifestations

- *Incidence*—it is rare and accounts for 7% of all osteosarcomas.
- *Site*—it is equal in maxilla and mandible. In the mandible, lesion is seen in body and in maxilla it occurs in antrum or alveolar ridge.
- *Symptoms*—swelling of a short history and is accompanied by pain. Affected tooth may become displaced or loose. Numbness of lip and chin may be

Fig. 16-39: Rapidly growing swelling seen in floor of mouth in osteosarcoma patient.

due to involvement of inferior alveolar nerve. There may be trismus and hemorrhage.

- *Sign*—there may be history of tooth extraction with nodular or polypoid reddish granulomatous appearing mass growing from tooth sockets. Expansion is very firm due to dense fibrous tissue which is produced. Initially, swelling is smoothly contoured and covered by normal mucosa (Fig. 16-40). When expansion becomes chronically traumatized, mucositis develops on surface. Later, the surface gets ulcerated and looks like whitish gray in color.

Fig. 16-40: Smoothly contoured swelling seen in maxillary anterior region in osteosarcoma patient (Courtesy Dr Pravin Lambade).

Radiographic Features

- *Periodontal ligament space widening*—there is symmetrical widening of periodontal ligament space in early stage of the disease.
- *Types*—it may develop into a frankly osteolytic stage, mixed stage, i.e. those which produce some bone and thirdly those which are almost entirely bone forming.

- *Frankly osteolytic*
 - *Margins*—lesions are unicentric and borders of the lesion are ill defined.
 - *Appearance*—there is moth eaten appearance.
 - *Cortical plate*—perforation and expansion of cortical margins by extension into sub-periosteal bone.
 - *Neurovascular canal*—mandibular lesion may destroy the cortex of neurovascular bundles. Alternatively, neurovascular canal may be symmetrically widened or enlarged.
 - *Lamina dura*—adjacent lamina dura may be destroyed.
 - *Pathological fracture*—pathologic fracture occurs more readily as in sarcoma extending more deeply into the bone.
 - *Maxillary sinus*—sarcomas which develop near the floor of maxillary antrum or nasal fossa result in destruction of bone with no demarcation on tumor from the air cavity.
 - *Spiking resorption of root*—there is resorption of root which results in tapered narrowing of the root.
- *Mixed (Fig. 16-41)*
 - The presence of new bone laid down deep to the periosteum may be slight or it may be gross and without any structures.
 - *Margins*—sarcomas with small amount of new bone formation usually present margins which are not well defined.
 - *Appearance*—there is evidence of bone formation as well as destruction. In some cases, there is a well defined area of bone destruction, with partially corticated borders and some bone within the tumor itself.
 - *Honeycomb appearance*—the bone within the radio-lucent area of destruction may take the form of strands, which may be few and intersecting, or may produce a more or less honeycomb appearance.

Fig. 16-41: Mixed type appearance seen in osteosarcoma patient. It also shows displacement and resorption of root.

- *Maxillary sinus and nasal fossa*—if the antrum or nasal fossae are involved, they are invaginated rather than infiltrated, since there is a complete bony covering over the tumor.
- *Frankly osteoblastic (sclerotic osteogenic sarcoma) (Fig. 16-42)*
- *Margins*—mixed lesion has ragged, ill defined borders and its radiographic pattern is the result of excessive bone production intermingled with radiolucent foci of bone destruction.

Fig. 16-42: Osteoblastic variety of osteogenic sarcoma showing radiopacity.

- *Granular appearance*—the sclerotic portion of mixed and opaque lesion may show vertical obliteration of trabecular pattern by new bone, impairing dense granular or sclerotic appearance.
- *Sunray appearance*—if the tumor has invaded the periosteum, many thin irregular spicules of new bone directed outwards and perpendicular to surface of the lesion are seen producing a 'sunray' appearance (Fig. 16-43).
- *Codman's triangle*—sometimes two triangular radiopacities project from the cortex and mark the lateral extremities of the lesion referred as 'Codman's triangle'. It is seen where the tumor breaks through the surface of the bone and it is the result of separation of the periosteum from the surface of the adjacent bone and subsequent ossification in the space formed between periosteum and bony surface.
- *Onion peel appearance*—on rare occasion, subperiosteal bone laid down in layers and it may take form of onion peel lamination.
- *Alveolar ridge*—there is also distortion of the alveolar ridge.

Fig. 16-43: Typical sunray appearance seen in osteogenic sarcoma.

Variant of Osteosarcoma

- *Peripheral (Juxtacortical)*
 - *Parosteal osteosarcoma*—it is attached to the cortex by short stalk. In this, there is no elevation of periosteum and no peripheral reaction. It is uncommon, extremely rare in the jaws and is characterized by slow growth. It has good prognosis due to low tendency of tumor for metastasis. It is treated by radical excision which results in low risk of recurrence.
 - *Periosteal osteosarcoma*—it arises within the cortex and elevate the overlying periosteum. It is an aggressive variant of parosteal type of osteosarcoma. There is occurrence of periosteal new bone formation. This may perforate the surface of periosteum and lesion may extend into surrounding soft tissue. In this, radical surgical excision with wide margin is the treatment of choice.
- *Extra-osseous*—osteosarcoma of soft tissue in absence of primary skeletal tumor and occur in breast, liver and kidney. It is highly malignant type of tumor.
- *Post-irradiation bone sarcoma*—it can develop after 3 years of radiation. It is dose related. If higher dose is given, there are more chances of sarcoma.

Diagnosis

- *Clinical diagnosis*—rapidly growing swelling of bone which is accompanied by pain and discomfort will give clue to diagnosis.
- *Radiological diagnosis*—periodontal ligament space widening, sunray appearance, Codman's triangles are typical radiological features of the osteosarcoma.
- *Laboratory diagnosis*—serum alkaline phosphatase level is increased in osteosarcoma. Biopsy shows atypical osteoblasts. Neoplastic osteoblasts are spindle shaped or polyhedral. Pleomorphism in size and shape of cells.

Differential Diagnosis

- **Carcinoma**—in frank osteolytic stage, this can be confused; but, carcinoma arising from oral mucosa has a tendency to extend along the surface of the bone more than sarcoma itself which originated within the bone. The absence of any soft tissue involvement may suggest its central nature. Sarcoma is expected to extend more deeply into the bone with more frequent pathologic fracture. Complete dissolution of continuity of the mandible may take place more quickly with sarcoma than carcinoma. Sarcoma is more likely to produce bone destruction in a more concentric manner since it starts in the substance of bone, instead on the surface.
- **Peripheral fibroma with calcification**—benign, slow growth.
- **Ossifying subperiosteal hematoma**—history of recent trauma.
- **Chondrosarcoma**—it usually occurs in older age and in maxilla.
- **Fibrous dysplasia**—these are well demarcated than osteosarcoma and have more uniform internal structures.
- **Osteomyelitis**—osteosarcoma is not associated with signs of infection.

Management

- **Surgery**—radical resection with amputation of bone can be carried out.
- **Adjuvant chemotherapy**—sometimes, adjuvant chemotherapy can be instituted.

Ewing's Sarcoma

It was first described in 1921 by James Ewing. It is also called as 'round cell sarcoma' or 'endothelial myeloma'. It is derived from mesenchymal connective tissue of bone marrow.

Origin

- **Endothelial element**—it may arise from endothelial elements in the marrow.
- **Neuroblastoma**—it may be a secondary deposit of neuroblastoma.
- **Marrow spaces**—it may arise from reticulum cell lining of the marrow spaces.
- **Metastatic tumor**—some considered it to be a metastatic tumor, the primary of which is located in different sites, including bronchus.

Clinical Features

- **Age and sex**—it occurs between the ages of 5 and 25 years with a male to female ratio of 2:1.

- **Site**—the bones affected are the long bone of extremities although the skull, clavicle, ribs, shoulder and pelvic girdles are involved. 10 to 15% occur in jaw, usually in mandible.
- **Progress**—it is a very rapidly growing highly invasive tumor with early and widespread metastasis.
- **Symptoms**—initially, intermittent pain which later becomes continuous and is associated with rapid growth of the tumor and enlargement of bone. During the attacks of pain the tumor enlarges visibly. Pain is associated with febrile attacks and leukocytosis.
- **Metastasis**—it usually metastasizes to other bones.
- **Signs**—the swelling is hard but occasionally, it may be soft and fluctuant. In the early lesion, when the tumor is intraosseous, swelling is firm. When the tumor breaks through the cortex, it spreads extensively in the soft tissues and form a soft mass which may ulcerate. Swelling is warm and tender.
- **Surface**—there may be hyperemia of the overlying tissues (**Fig. 16-44**), suggesting inflammatory condition.
- **Other features**—facial neuralgias, lip paresthesia are present. Teeth may become mobile and paresthesia may develop. There may be trismus, epistaxis, exophthalmos and sinusitis.

Fig. 16-44: Extraoral swelling showing hyperemia of overlying tissue of Ewing's sarcoma.

Radiographic Features

- **Radiodensity**—it is ill-defined destructive radiolucent, lesion which may be unilocular or multilocular (**Fig. 16-45**).
- **Site**—most commonly seen in mandibular posterior area.
- **Margins**—it has ill-defined margins and is never corticated. In advanced cases, bone is destroyed in

uneven fashion, resulting in ragged borders. Areas of sclerosis may be found around the margins of the lesion with mottled rarefaction.

- *Onion skin appearance*—if it penetrates the cortex, it may stimulate the periosteum to produce thin layers of bone which are laid down in layers more or less, parallel to shaft: resulting in laminated or onion skin effect along the bone surface.
- *Sunray appearance*—in advanced cases, where osteophytes formation is present, it may present as sunray appearance.
- *Effect on surrounding structures*—it may cause pathologic fracture. There may be destruction of lamina dura and the supporting bone of adjacent teeth. Mandibular neurovascular canal, inferior border of mandible and alveolar cortical plate may be destroyed.

Fig. 16-45: Radiolucent lesion seen in ramus area in Ewing sarcoma.

Diagnosis

- *Clinical diagnosis*—intermittent pain in the bone with rapidly growing swelling may suspect this lesion.
- *Radiological diagnosis*—onion skin appearance is seen.
- *Laboratory diagnosis*—biopsy shows cellular neoplasm which is composed of solid sheets or masses of small round cells with very little stroma, although few connective tissue septa can be seen.

Differential Diagnosis

- *Osteomyelitis*—in osteomyelitis, there is presence of sequestra within the confines of lesion.
- *Eosinophilic granuloma*—it is associated with laminar periosteal bone reaction whereas Ewing's sarcoma does not produce laminar bone reaction.
- *Osteosarcoma, chondrosarcoma*—these are difficult to differentiate radiologically from Ewing's sarcoma. In it, histopathological investigation is conclusive.

Management

- *Combination therapy*—surgery combined with multidrug chemotherapy gives more survival rate nowadays.

Vascular Tumors

Malignant Hemangioendothelioma

It is a neoplasm of mesenchymal origin which is angiomatous in origin and derived from the endothelial cells.

Clinical Features

- *Age and sex*—it has slight predilection for females. It can arise at any age and has been found at birth also.
- *Site*—it may occur anywhere in the body but most commonly found in skin and subcutaneous tissues. In oral cavity, it can occur on lips, palate, gingiva, tongue and centrally within the maxilla and mandible.
- *Symptoms*—localized swelling with pain may be the feature of lesion.
- *Appearance*—it appears as flat or slightly raised lesion of varying size, dark red or bluish red in color.
- *Sign*—lesion can be ulcerated and show a tendency to bleed even after slight trauma.
- *Bone destruction*—bone may be involved by tumor producing a destructive process.

Diagnosis

- *Clinical diagnosis*—not so specific.
- *Laboratory diagnosis*—biopsy shows endothelial cells arranged in columns. Capillary formation is poorly defined, although anastomosing vascular channels may be discerned. The individual cells are pleomorphic large polyhedral or slightly flattened, with a faint outline and a round nucleus with multiple minute nucleoli.

Management

- *Surgery*—surgical excision of the lesion should be carried out.
- *Radiation*—surgery and X-ray radiation can be given.

Angiosarcoma

Angiosarcomas are malignant vascular tumors that comprise only 2% of soft tissue sarcoma. It is very rare in all sites including oral cavity.

Clinical Features

- *Site*—on the head it affect scalp. In the oral cavity, it appears in lip, palate, tongue, floor of mouth, cheek and gingivae. Mandible is more commonly affected than maxilla.
- *Appearance*—it appears as rapidly growing lesion that tends to ulcerate.

- *Sign*—margins of the lesion are ill defined. Surface is firm on palpation. There may be spontaneous bleeding seen from the lesion.
- *Lymph nodes*—regional lymph nodes are usually enlarged.

Radiological Features

- *Conventional film*—ill-defined ragged destruction of the bone occurs.
- *CT scan*—it reveals extension of soft tissue.

Diagnosis

- *Clinical diagnosis*—no specific.
- *Radiological diagnosis*—ill-defined destruction of bone can occur.
- *Laboratory diagnosis*—there are irregular vascular channels lined by endothelial cells that are often pleomorphic and may show numerous mitoses.

Management

- It is done by combination of surgery and radiation therapy.

Tumors of Neural Tissues

Neuroblastoma

It is a rare malignant tumor of the adrenal gland. It sometimes arises in the nerves or ganglia of the sympathetic system in the neck, thorax or abdomen. After leukemia, it is the commonest malignancy of children.

Clinical Features

- *Age*—it usually occurs in children under the age of 5 years.
- *Site*—oral cavity and nasal sinuses are involved. Oral involvement is usually due to metastasis and it occurs in mandible and maxilla.
- *Symptoms*—there is swelling, displacement of teeth and neurological symptoms.
- *Metastasis*—skull is one of the commonest sites for metastases. Metastases in bone tend to be multiple.

Radiological Features

- *Radiodensity*—some cases reveal areas of bone destruction with evidence of new bone formation within them and beneath the periosteum.
- *Sunburst appearance*—in some cases, there are spicules of bone within the soft tissue mass associated with bone destruction, these are roughly perpendicular to the surface of the bone and may resemble the 'sunburst' appearance.

- *Spoke wheel appearance*—in some cases, the spicules of bone or trabeculae are arranged radially in a rough architecture of wheel or spokes. The margins of the area of bone destruction are irregular and do not present any cortication.
- *Mottle area of decalcification*—a mottled area of decalcification is seen in some of the cases of metastases and with the passage of time, the lesion tends to become obviously osteolytic. Such areas may be localized or diffuse.

Diagnosis

- *Clinical diagnosis*—if neurological symptoms with swelling in jaw is present then neuroblastoma should be suspected.
- *Radiological diagnosis*—spoke wheel pattern, sunburst appearance are present.
- *Laboratory diagnosis*—biopsy shows degree of differentiation. It consists of small round cells arranged merely in diffuse masses. In some cases, differentiating cells begin to form groupings; generally referred to as rosettes and the cell themselves develop neurofibrillary processes.

Management

- *Surgery and radiation*—surgery and radiation is the treatment of choice in neuroblastoma.

Neurofibrosarcoma

It is also called as '*malignant Schwannoma*', '*malignant peripheral nerve sheath tumor*', '*neurogenic sarcoma*'. It arises from nerve tissue, especially from nerve sheath cells. It is rare in oral cavity.

Peripheral nerves are nerves that receive messages from the central nervous system (brain and spinal cord) leading them to stimulate voluntary movement. Neurofibrosarcoma, also known as peripheral nerve sheath tumor, is a malignant tumor that develops in the cells surrounding these peripheral nerves. It can sometimes arise in patients with neurofibromatosis.

Clinical Features

- *Sex and age distribution*—It usually occurs in 3rd and 6th decade with no sex predilection.
- *Common sites*—it occurs on lips, gingiva, palate and buccal mucosa. In central tumor mandible is more affected than maxilla.
- *Symptoms*—only complaint is the presence of mass and in some cases, pain or paresthesia may be present.
- *Appearance*—tumor mass sometimes exhibits rapid growth in patient.

Radiological Features

- **Radiodensity**—it reveals diffuse radiolucency is the characteristic feature of a malignant infiltrating neoplasm.
- **Appearance**—in some cases, it may appear as a smooth radiolucency. When the tumor originates from the inferior alveolar nerve, there is dilatation of the mandibular canal.

Diagnosis

- **Clinical and radiological diagnosis**—it is difficult to make clinical and radiological diagnosis.
- **Laboratory diagnosis**—biopsy shows plumps of spindle shaped cells arranged in streams and cords with random nuclei. It exhibits variation in degree of malignancy, i.e. tumors that are relatively acellular, show little cellular pleomorphism. Tumors that are highly cellular shows pleomorphism and bizarre mitotic activity.

Management

- **Radical surgical resection**—this is the treatment of choice in neurofibrosarcoma.
- **Adjuvant radiotherapy and chemotherapy**—this can be given in combination with surgical resection.

Muscle Tumors

Leiomyosarcoma

It is a malignant tumor of smooth muscle origin.

Clinical Features

- **Age and sex**—it can occur at any age with no sex predilection.
- **Site**—the most common site is uterine wall and gastrointestinal tract. It is very rare in oral cavity and if present, it is seen commonly on cheeks and floor of mouth.
- **Symptoms**—the lesion appears as painful swelling.
- **Appearance**—the mass is nonspecific in appearance. Secondary ulceration of mucosal surface can be present.
- **Metastasis**—they tend to metastasize through hematogenous route.

Diagnosis

- **Clinical and radiological diagnosis**—nonspecific appearance.
- **Laboratory diagnosis**—there is presence of mitosis, nuclear pleomorphism, hyperchromatism and bizarre cell forms. Proliferating smooth muscles cells are arranged as interlacing bands or cords.

Management

- **Surgical excision**—radical surgical excision should be carried out.
- **Adjuvant radiotherapy**—it should be given in some cases.

Rhabdomyosarcoma

It is a malignant neoplasm of skeletal muscle origin and it is uncommon in oral cavity.

Types (Histological)

- **Pleomorphic**—it occurs most commonly in extremities and in older individuals.
- **Alveolar**—it is found in head and neck region and in extremities, with early age of occurrence.
- **Embryonal**—it is found in the genitourinary tract and in nasopharynx, with cases reported in oral cavity in the upper and lower labial folds.
- **Botryoid**—is a malignant tumor of vagina, prostate and base of bladder in young children.

Clinical Features

- **Age**—it is most common soft tissue sarcoma in children and adolescents. It is exclusively found in males.
- **Site**—it is a mass occurring in any region of the head and neck where striated muscle or its mesenchymal progenitor cells exist. Intraorally, the tonsils and soft palate are most frequently involved.
- **Symptoms**—depending upon of the size of lesion, there may be divergence of eyes, abnormal phonation, dysphagia, cough, aural discharge or deviation of the jaw.
- **Appearance**—typically, it is a rapidly growing soft tissue mass. It forms polypoid fleshy growth beneath the mucous membrane, with club-like extensions at periphery.
- **Signs**—the overlying skin is usually erythematous or telangiectatic.
- **Spread**—it may spread by either lymphatic or hematogenous routes.
- **Metastasis**—the lesions are occasionally ulcerated and may invade the underlying bone and develop distant metastasis.

Diagnosis

- **Clinical**—rapidly growing soft tissue mass with polypoid fleshy growth.
- **Laboratory diagnosis**—in pleomorphic rhabdomyosarcoma, spindle cells are arranged in haphazard manner. The nuclei are situated often in an expanded end of cells. The 'racquet cell', 'Strap-like' and 'ribbon' cells typically show process of long streaming cytoplasm. In *alveolar rhabdomyosarcoma*, epithelium cells

appear to be 'dropping off' from collagen. In *embryonal rhabdomyosarcoma*, four types of cell, i.e. eosinophilic spindle cells, round eosinophilic cells, broad elongated eosinophilic cells and small, round spindle cells with dark staining nuclei and little cytoplasm are present.

Management

- *Local surgical excision*—surgical excision of the tumor should be carried out.
- *Multiagent chemotherapy*—it consists of vincristine, actinomycin D and cyclophosphamide.
- *Postoperative radiation therapy*—radiation therapy should be given postoperatively.
- *Prognosis*—initially, it has poor prognosis. But nowadays due to advent of multimodal therapy, prognosis is improved dramatically.

Alveolar Soft Part Sarcoma

It is rare neoplasm of uncertain histogenesis. It is thought to be of striated muscle origin.

Clinical Features

- *Age and sex*—it is predominantly a tumor of females, occurring usually in teens or early twenties. Occasional cases also occur in older patients.
- *Site*—head and neck region are common site. The orbit and tongue are most common in head neck location.
- *Appearance*—they are usually slow growing, well circumscribed masses.

Diagnosis

- *Clinical*—not possible to diagnose or suspect clinically.
- *Laboratory diagnosis*—biopsy shows group of large polygonal cells which are arranged around alveolar spaces. Cells have abundant granular eosinophils cytoplasm.

Management

- *Radical surgical excision*—due to the high recurrence rate, radical surgical excision is the treatment of choice.

Tumors of Lymphoid Tissues

Hodgkin's Lymphoma

It is lymphoproliferative disorders arising from lymph nodes and from lymphoid components of various organs. It is neoplastic proliferation of lymphopoietic portion of reticuloendothelial system. It involves the cells of either the

lymphocytic or histiocytic series, in varying degrees of differentiation and occurs in an essentially homogenous population of a single cell type.

It was first described by British pathologist, Thomas Hodgkin in 1832. It is characterized by painless enlargement of lymphoid tissue throughout the body.

The exact cause of Hodgkin's lymphoma is not known. Some author suggested that virus like herpes and oncornavirus can cause Hodgkin's lymphoma.

Types (Histological)

- *Lymphocyte predominant*—abundant lymphocytes, few plasma cells, occasional Reed-Sternberg cell, localized involvement of one side of diaphragm and most favorable prognosis.
- *Mixed cellularity*—lymphocytes, plasma cells, eosinophils, easily identified Reed-Sternberg cell.
- *Nodular sclerosis*—sparse lymphocytes, stromal cells, fibrosis and numerous but bizarre Reed-Sternberg cells. It has poor prognosis.
- *Lymphocyte depletion*—lymphocytes, plasma cells, eosinophils with localized involvement.

Clinical Features

- *Age and sex*—it is characterized by a bimodal age incidence, peak one in young adults and the second in the 5th decade of life with equal distribution between sexes.
- *Onset*—the onset is insidious, usually with enlargement of one group of superficial nodes. The cervical lymph nodes are usually the first to be involved but the disease may start in the mediastinal, axillary, abdominal, pelvic or inguinal lymph nodes.
- *Symptoms*—the involved nodes are painless. Generalized weakness, loss of weight, cough, dyspnea and anorexia are seen. Pain in back and abdomen owing to splenic enlargement, due to pressure of enlarged nodes or involvement of vertebrae.
- *Signs*—the lymph nodes are discrete and rubbery in consistency with overlying skin being freely mobile (**Fig. 16-46**). Splenomegaly is usually seen in later stage. Some patients may manifest pruritis.
- *Pel Ebstein fever*—characteristic features of this disease are *Pel-Ebstein fever*, a cyclic spiking of high fever and generalized severe pruritis of unknown etiology.
- *Effect on surrounding structures*—pressure of enlarged lymph nodes on adjacent structures may cause dyspnea, dysphagia, venous obstruction, jaundice and paraplegia.

Clinical Stages (Ann Arbor Staging)

- *Stage I*—involvement of single lymph node region or extra-lymphatic sites.

Fig. 16-46: Enlargement of lymph nodes seen in Hodgkin's lymphoma (Courtesy Dr Milind Chandurkar).

- *Stage II*—involvement of two or more lymph node regions or an extra-lymphatic site and lymph node region on the same side of diaphragm.
- *Stage III*—involvement of lymph node region on the both sides or without extra-lymphatic involvement or involvement of spleen or both.
- *Stage IV*—diffuse involvement of one or more extra-lymphatic tissues, e.g. liver or bone marrow.
- *Subdivision*—all the above stages are subdivided into A and B categories depending on whether they have systemic symptoms such as weight loss, fever, night sweats. A—absence of systemic signs and B—presence of systemic signs.

Oral Manifestations

- *Incidence*—primary jaw lesions are uncommon.
- *Secondary effect*—secondary effect can be seen in oral cavity in the form of infection due to reduced host immune response.
- *Appearance*—it may appear in the oral cavity as an ulcer or a swelling or as an intra-bony lesion which presents as a hard swelling.

Radiographic Features

- *Site*—it is rarely seen in jaws. The common regions are the posterior maxilla and mandible.
- *Appearance*—malignant lymphoma arising in the oral cavity spreads to bone and cause irregular bone loss to the area of the lesion. There are radiolucent areas separated from each other by normal appearing bone which later become confluent, unless treatment is carried out.
- *Margins*—typically, the radiolucent lesions have diffuse ill defined margins which suggest infiltration of bone.
- *Osteoblastic type*—osteoblastic type is uncommon in jaws, but it is seen in the vertebrae and pelvis. In it, there is frank sclerosis with filling of the marrow spaces by bone. It presents as grayness or whiteness which is abnormal. The margins may be well defined and sharp or irregular and trailing off gradually into the normal bone.

Diagnosis

- *Clinical diagnosis*—discrete enlargement of lymph node which is rubbery in consistency with some systemic signs.
- *Radiological features*—there is foci of radiolucency seen in the jaw.
- *Laboratory diagnosis*—it is characterized by replacement of normal lymph node architecture by an admixture of malignant lymphoid cells and non-neoplastic inflammatory cells. Characteristic *Reed Sternberg cells* are present. Multinucleated giant cells are also present. There is also presence of anemia which is normocytic and normochromic. ESR is raised. There is also raised level of LDH.

Differential Diagnosis

- *Non-Hodgkin's lymphoma*—Hodgkin's lymphoma is differentiated from non-Hodgkin's lymphoma by the presence of cells known as Reed-Sternberg cells which have paired as mirror nuclei and prominent nuclei.

Management

- *Radiotherapy*—irradiation treatment 3500-4000 rads/week over the involved region plus all adjacent sites been given in stage I and II. It is also given after chemotherapy, to sites where there was originally bulk disease.
- *Chemotherapy*—it is given in stage III and IV. Usually combination is given. First combination is MOPP, i.e. mechlorethamine (6 mg/m² IV on day 1 and day 8), oncovin which is also called as vincristine (1.4 mg/m² IV on day 1 and 8), procarbazine (100 mg/m²) orally from day 1 to 14) and prednisone (40 mg/m² orally from day 1 to 14). MOPP combination given in six courses with no drugs is given from day 15 to 28. Second combination is ABVD regimen, i.e. adriamycin (25 mg/m² IV bolus on day 1,8 and 14), bleomycin (10 mg/m² bolus on day 1,14), vinblastine (6 mg/m² IV bolus on day 1,14) and decarbazine (375 mg/m² IV bolus on day 1,14). The cycle should be repeated on 20th day.
- *Combination*—a combination of radiotherapy and chemotherapy may increase the overall response and long term survival but, it is associated with delayed complications like leukemia, gonadal atrophy and avascular necrosis of bone.
- *Splenectomy*—splenectomy is advocated in many patients, except with stage IV disease.

Non-Hodgkin's Lymphoma

It is also called as '*lymphosarcoma*'. In this group, there is neoplastic proliferation of lymphoid cells, usually affecting the B-lymphocytes. Unlike Hodgkin's lymphoma, the

disease is frequently widespread at the time of diagnosis, often involving not only the lymph nodes but also bone marrow, spleen and other tissue. Early involvement of bone marrow is typical of this lymphoma.

Types (Histological)

- *Nodular*—neoplastic cells tend to aggregate in such a way that large clusters of cells are seen.
- *Diffuse*—there is monotonous distribution of cells with no evidence of nodularity or germinal center pattern.

Etiology

- *Viral*—the etiology is unclear but herpes virus and Epstein barr etiology has been suggested.
- *Immunological*—there may be induced immunologic effect permitting a malignant clone to proliferate.

Clinical Features

- *Age and sex*—it affects persons of all ages from infants to the elderly. But is commonest in middle age group. Males are affected more commonly than the females.
- *Onset*—the onset of symptoms may be insidious. Painless lymph node enlargement of abdominal and mediastinal region are the most common finding. Very often the first group of lymph nodes affected may be cervical, axillary or inguinal.
- *Symptoms*—the patient complains of tiredness, loss of weight, fever and sweating. Pain is the main symptom of bone involvement which may present as a pathological fracture. Patient may complain of abdominal pain, nausea, vomiting, diarrhea or intestinal obstruction which may occur due to involvement of gastrointestinal tract. Pressure effect of lymphoma may cause dysphagia, breathlessness, vomiting, intestinal obstruction or ascites and paraplegia.
- *Signs*—if liver and spleen are involved, hepatosplenomegaly is present. The growth is fleshy and is prone to ulceration.

Oral Manifestations

- *Site*—occurrence of malignant lymphoma in oral cavity is rare; when present it is more often found to arise from the tonsils. Other sites which can be involved are palate, buccal mucosa and gingiva.
- *Appearance*—palatal lesions have been described as slow growing, painless, bluish soft tissues mass which may be confused with minor salivary gland tumors.
- *Symptoms*—paresthesia of mental nerve has been reported. Sometimes there is pain and neuralgia in the region of 2nd and 3rd division of 5th cranial nerve.

- *Sign*—in rare cases necrotic proliferation of palate may also be seen. The swelling may ulcerate and discolor in some cases.

Radiographic Features

- *Appearance*—as the disease progresses small radiolucent foci scattered throughout the area may be seen. Subsequent radiographs of the expanding lesion will show that these small foci have coalesced to form large multilocular moth eaten radiolucency with poorly defined margins.
- *Margins*—lesion blends imperceptibly with adjacent normal bone, in most of the cases.
- *Effect on surrounding structures*—lesions may cause marked expansion of bone. Erosion and perforation of cortex may occur.
- *Maxillary sinus involvement*—if the lesion involves maxillary sinus, possible opacification with breached cortical walls and associated paracentral or intracentral mass.
- *Teeth*—cortices of unerupted tooth buds and lamina dura of adjacent teeth are lost. Teeth may be resorbed.

Diagnosis

- *Clinical diagnosis*—bluish color mass of the palate with multiple lymph node involvement may suspect the diagnosis of non-Hodgkin's lymphoma.
- *Radiological features*—expansion of bone with radiolucency is present.
- *Laboratory diagnosis*—blood count usually shows hypersplenism or hemolytic anemia. The reduced WBC and RBC counts are seen along with reduced hemoglobin levels and reticulocytosis. In some cases, there may be slight increase in lymphocytes and thrombocytopenia. Moderate degree of anemia will also present when there is considerable bone marrow involvement. Some very aggressive high grade non-Hodgkin's lymphomas are associated with very high urate levels which can precipitate renal failure.

Differential Diagnosis

- *Multiple myeloma*—Bence Jones proteins are present in urine, borders of lesion are usually well defined.
- *Metastatic carcinoma*—history of primary tumor.
- *Ewing's sarcoma*—it occurs in younger age group.
- *Osteosarcoma*—it can be differentiated by clinical features.

Management

- *Chemotherapy*—when diagnosed in late stages, chemotherapy is the treatment of choice. In most cases single agent chemotherapy (chlorambucil) is usually

given. Combination with prednisolone is also useful. A combination of cyclophosphamide, doxorubicin, vincristine, bleomycin with prednisolone is commonly used.

- **Radiotherapy**—radiotherapy is used to treat local disease and the patient is given a total dose of 150 rads spread over a period of five weeks.
- **Transplantation**—studies of autologous stem cell transplantation are in progress.

Primary Reticular Cell Sarcoma

It is also called as '*primary lymphoma of bone*'. Most of cases of primary reticular cell sarcoma arise from non-Hodgkin's lymphoma. It may be caused by immunosuppression and viral agents. Primary lymphoma of bone is usually seen in AIDS patient.

Clinical Features

- **Age and sex**—it can occur in any age group but it is common amongst young adults under the age of 40 years. It is common in male as compared to females.
- **Sites**—it most commonly seen in femur, tibia and humerus.
- **Symptoms**—most common complaint is pain. There is also presence of localized swelling of the involved bone. Patient may also complaint of weight loss, fever, and night sweats.
- **Sign**—regional lymphadenopathy is usually present.

Oral Manifestations

- **Site**—it is not common, but it usually occurs more in mandible than maxilla.
- **Symptoms**—pain is common complaint and usually present for years and more. There is also presence of expansile mass.
- **Sign**—the oral mucosa over the involved bone seldom gets ulcerated but at times, appears diffusely inflamed.
- **Teeth**—the teeth usually become exceedingly loose, owing to destruction of bone.
- **Maxillary lesion**—when the lesion involves maxilla, there may be evidence of expansion of the bone as well as symptoms of nasal obstruction due to superior growth of tumor into the floor of nasal cavity.

Radiographic Features

- **Moth eaten appearance**—there is diffuse radiolucency involving the alveolar bone which may present destruction of the supporting bone of the teeth. It may present a moth eaten appearance.
- **Margins**—in the jaw, the tumor usually gives rise to an area of bone destruction with margins suggestive of infiltration.

- **Periosteal reaction**—there may be periosteal reaction. New bone formation may be linear in character or amorphous and radiating spicules of bone are seen which stand more or less perpendicular to the jaw.

Diagnosis

- **Clinical diagnosis**—a primary focus is single bone. Systemic symptoms with local pain with regional lymphadenopathy will give clue to the diagnosis.
- **Radiological diagnosis**—moth eaten appearance with periosteal reaction is present.
- **Laboratory diagnosis**—primary cells of tumor are identical with that of the soft tissue tumors. There may be inflammatory cell infiltration which can lead to confusion in the diagnosis of the lesion. The individual cells are mixed with both mature appearing lymphocytes and large histiocytoid lymphoblast. Many patients have increased level lactate dehydrogenase.

Management

- **Surgical ablation**—surgical ablation is done.
- **Radiation**—X-ray radiation is the treatment of choice. The 5 year survival rate is between 50 to 60%.

Mycosis Fungoides

It is derived from T lymphocytes. It is also called as '*T cell lymphoma*'. This tumor has got propensity to invade the epidermis of skin (epidermotrophism).

Clinical Features

- **Age and sex distribution**—it usually affects middle aged adult with male predilection.
- **Size**—it varies in size from few millimeters to centimeters in diameter.
- **Site**—it involves lymph nodes, spleen and liver.
- **Eczematous stage**—these are well demarcated scaly erythematous patches. Patient complains of pruritus.
- **Plaque stage**—these appear after eczematous stage in which erythematous patches become elevated red lesion.
- **Tumor stage**—plaque grows and become papules and nodules. In this stage visceral involvement is seen.
- **Sézary syndrome**—it is dermatopathic T cell leukemia. Patient is suffering from exfoliative erythroderma, lymphadenopathy, and hepatomegaly and splenomegaly.

Oral Manifestation

- **Site**—tongue, palate, buccal mucosa, lip, gingiva and tonsils.
- **Appearance**—oral lesions can be the first manifestation and sometimes, appear after the skin lesions have been treated and remitted. The lesions appear as indurated areas, nodules or erythematous ulceration (**Fig. 16-47**).

Fig. 16-47: Indurated area in the maxillary tuberosity region which later on histologically diagnosed as mycosis fungoides.

Diagnosis

- *Clinical diagnosis*—eczematous or plaque lesion on the skin.
- *Laboratory diagnosis*—biopsy shows dense infiltration of lymphoid cells with irregularly shaped nuclei. In some cases, nuclei are so convoluted that they are described as cribriform.

Management

- *Early stage*—topical nitrogen mustard, electron beam therapy and photochemotherapy (PUVA) are used in early stage.
- *Extracorporeal photopheresis*—extracorporeal photopheresis is used in this stage. This involves ingestion of photoactive drug 8-methoxypsoralen followed by removal of patient's blood and separating red and white blood cells. The white blood cells are irradiated outside the body with ultraviolet radiation and then infused back to patient. This will generate immunological response to patient abnormal lymphocytes.

Burkitt's Lymphoma

It was described by Dennis Burkitt in 1950. It is also called as 'African jaw lymphoma'. It is a lymphoreticular cell malignancy. In the African form jaw involvement is 75% and in cases of the American form, abdomen involvement is more common. It is a B-cell neoplasm. Difference between African form and American form is described in **Table 16-2**.

Etiology

- *Epstein-Barr virus (EBV)* which also causes nasopharyngeal carcinoma and infectious mononucleosis is considered to be the etiological factor. There are higher EBV antibody levels in patients of Burkitt's lymphoma.

Clinical Features

- *Age and sex*—peak incidence is in children between 6 to 9 years. Males are affected more commonly than the females, with a ratio of 2:1.
- *Site distribution*—more are found in maxilla than in mandible, where it may spread rapidly to the floor of the orbit. Almost always occurs in molar area. In the African form, more than one quadrant is involved while in the American form, only one quadrant is involved.
- *Onset and progress*—the most important hallmark of this tumor is the fast growth with a tumor doubling time of less than 24 hours.
- *Symptoms*—the most common presenting features are swelling of the jaws, abdomen and paraplegia. It is painless.
- *Sign*—peripheral lymphadenopathy is common.
- *Prognosis*—it is rapidly fatal in the absence of treatment, with death occurring within 6 months.

Oral Manifestations

- *Onset and extent*—it begins generally as a rapidly growing tumor mass of the jaws, destroying the bone

Table 16-2: Difference between endemic (African) and non-endemic (non-African) form

Features	Endemic form	Non-endemic form
Age	Young children	Adolescents and young adults
Nodal tissue	Secondarily involve the extra-nodal tissue	Lymph nodes, lymphoid tissue and bone marrow
Sex	No sex predilection	American male predilection
Jaw	Rapidly growing tumor mass of jaws, destroy bone and cause loosening of teeth	Jaw uncommon
Visceral involvement	Visceral organ involvement is less frequent	Visceral organ involvement is common
Nerve involvement	Maxillary and mandibular nerve not involved	Not common
Antibody titre	Antibody titre is negative	Antibody titre is positive

with extension to involve maxillary, ethmoid and sphenoid sinus as well as orbit.

- **Symptoms**—loosening or mobility of permanent teeth. There is gross distortion of the face due to swelling. Paresthesia and anesthesia of inferior alveolar canal or other sensory facial nerves are common.
- **Signs**—gingiva and mucosa adjacent to the affected teeth become swollen, ulcerated and necrotic. As the tumor mass increases, the teeth are pushed out of their sockets. Swelling of the jaw occurs and it may cause facial asymmetry. They are capable of blocking nasal passages, displacing orbital contents and eroding through skin. There is derangement of arch and occlusion. There may be large quantity of mass protruding into the mouth, on the surface of which may be seen rootless, developing permanent teeth.
- **Spread**—once the tumor perforate the bone, it is initially confined by the periosteum, but subsequently it spreads to the soft tissues of the oral cavity and face where rapid tumor growth soon obliterates the entire face and skin becomes tense and shiny.

Radiographic Features

- **Moth eaten appearance**—small radiolucent foci scattered throughout the affected area. These small foci coalesce and form a multilocular moth eaten appearance. Focal areas of radiolucency are darker and sharper than the shadow of the marrow space lined by normal bony trabeculae.
- **Sunray appearance**—if periosteum is elevated, it will produce sunray appearance.
- **Margins**—margins are ill defined and non-corticated.
- **Shape**—they expand rapidly and are ballooned shaped.
- **Teeth**—Lesions are osteolytic with loss of lamina dura about the erupted teeth and crypts of developing teeth are enlarged. Erupted teeth in the area are grossly displaced, as are the developing tooth crypts.
- **Effect on surrounding structures**—they expand very rapidly and breach its outer cortical limits, causing gross balloon-like expansion with thinning of adjacent structures and production of soft tissue mass adjacent to the osseous lesion. Inferior border of mandible is thinned and later destroyed. Erosion and perforation of the cortex is seen. In some cases, orbit is involved and there is displacement of orbital content.
- **Maxillary sinus**—in the maxilla, there is blurring of shadow of antrum.

Diagnosis

- **Clinical diagnosis**—swelling of the jaw and abdomen with peripheral lymphadenopathy can give clue to the diagnosis.

- **Radiological diagnosis**—moth eaten appearance is seen with loss of lamina dura around the teeth.
- **Laboratory diagnosis**—monotonous sea of undifferentiated monomorphic lymphoreticular cells, usually showing abundant mitotic activity. There is also hyperchromatosis and loss of cohesiveness. Characteristic 'starry sky' appearance is seen.

Differential Diagnosis

- **Non-Hodgkin's lymphoma**—it occurs in older age groups.
- **Cherubism**—it does not breach the bony borders.
- **Osteosarcoma**—it is distinguishable from clinical features. On radiograph, osteoblastic activity is visible.

Management

- **Cytotoxic drugs**—cytotoxic drugs like cyclophosphamide 40 mg/kg in single IV administration and repeated about 2 weeks later. Vincristine and methotrexate have been successful in some cases.
- **Multiagent chemotherapy**—combination of drugs such as cyclophosphamide, vincristine and methotrexate give better results than any single drug. Majority of patients show dramatic response to the therapy. The swelling regresses and the displaced teeth return to their normal position within 1 to 2 weeks.

Leukemia

It is also called as 'leucosis'. It is defined as a neoplastic proliferation of WBC in bone marrow, usually in circulating blood and sometimes in other organs such as liver, spleen and lymph nodes. Presence of leukemic cells in bone marrow results in impairment of normal hemopoiesis with resultant anemia, granulocytopenia and thrombocytopenia. Leukemia is a progressive and fatal condition causing death from hemorrhage and infection. There is presence of excessive number of abnormal cells in the peripheral blood but leukemia is considered a primary disorder of bone marrow.

Types

- **'Stem' or 'blast' cell leukemia**—when the leukemic cells are too immature to be classified as to cell type, the leukemia is termed as 'stem' or 'blast' cell leukemia.
- **Subleukemia**—when the total WBC is normal and leukemic cells are seen in the peripheral blood is termed as subleukemia.
- **Aleukemia**—when no abnormal leukocytes are found in the peripheral blood (i.e. they can be found only in the bone marrow), the term aleukemia is used.
- **Leukemoid reaction**—when the peripheral blood picture in non-leukemic patient resembles that of leukemia, it is called a leukemoid reaction. In this, absolute neutrophil count remains above 30,000/mm³.

Classification

Acute

- *Acute lymphoblastic leukemia*
 - L_1 —Acute lymphoblastic (principally pediatric)—in it, small cells predominate and nuclei are generally round.
 - L_2 —Acute lymphoblastic (principally adults)—cells are heterogeneous in size and sharp in features, nuclei often show cleft.
 - L_3 (Burkitt's)—there is homogenous population of large cells. Nuclei are round to oval with prominent nucleoli.
- *Acute non-lymphoblastic or myeloid leukemia*
 - M_1 —Myeloblastic (without maturation)—myoblasts predominate with distant nucleoli, few granules are present.
 - M_2 —Myeloblastic (with maturation)—myeloblast and promyelocytes predominate and Auer rods are seen.
 - M_3 —Promyelocytic—hypergranular promyelocytes often with Auer rods are seen.
 - M_4 —Myelomonocytic—myelocytic and monocytic differentiation evident, myeloid elements resemble peripheral monocytosis.
 - M_5 —Monocytic—promonocytes or undifferentiated blast.
 - M_6 —Erythroleukemia—bizarre, multinucleated, megaloblastic erythroblast predominate.
 - M_7 —Megakaryocytic—pleomorphic undifferentiated blast cells with anti-platelet antibodies, myelofibrosis are present.

Chronic

- *Chronic lymphatic leukemia* (lymphogenous, lymphocytic) involving lymphocytes series.
- *Chronic myeloid leukemia* (myelogenous, myelocytic) leukemia involving granulocytes series.

Etiology

- *Virus*—Epstein-Barr virus, herpes-like virus and HTLV (human T-cell leukemia virus) have been considered to be the etiological agents responsible for leukemia.
- *Radiation and atomic energy*—if given over the dose of 100 rads, it is known to significantly increase the risk of leukemia. Leukemia among radiologists and Japanese exposed to the atomic blast are more, as compared to other population. It is also common in patients receiving X-radiation for rheumatoid spondylitis.
- *Chemical agents*—chronic exposure to aniline dyes; benzene and phenylbutazone have been recognized to be associated with leukemia. Usually in these patients pancytopenia due to marrow hyperplasia occurs prior to leukemia.

- *Anticancer drugs*—patient treated with anticancer drugs like melphalan and chlorambucil have an increased risk of developing leukemia, usually of acute myelocytic variety.
- *Genetic and chromosomal factors*—Philadelphia chromosome is found in about 15% of cases of acute lymphocytic leukemia. It suggests that if one set of identical twins develop leukemia before the age of 6 years, the risk of disease in other twins is 20%.
- *Immunological deficiency syndrome*—the persons suffering with Wiskott-Aldrich syndrome, Down syndrome, Bloom syndrome, Schwabach syndrome, and Klinefelter syndrome can also develop leukemia.

Acute Leukemia

Acute leukemia is a disorder in which there is a failure of maturation of leukocytes. As a result, there is an accumulation of immature cells within the bone marrow and later in the blood. It is the most common type of leukemia, except in children (in whom acute lymphoblastic leukemia is more common).

Etiopathogenesis

- *Leukemic blast*—there is a block in differentiation of leukemic and stem cells. Thus, accumulation of leukemic blast in acute leukemia results primarily from failure of maturation into functional stage.
- *Suppression of stem cells*—as leukemic blast accumulates in the marrow, they suppress the normal hematopoietic stem cells. The mechanism is not fully understood. Suppression part is related to physical replacement of normal precursor cells by expanded clones of leukemic cells.
- *Clinical manifestation*—clinical manifestations result from paucity of normal red cells, white cells and platelets.

Clinical Features

- *Age and sex*—it is more common in children and young adults between the age of 15 and 39 years. Males are affected more commonly than females with a ratio of 3:2. Acute lymphoblastic leukemia is seen in children.
- *Onset*—there is abrupt stormy onset with pyrexia and enlargement of spleen.
- *Symptoms*—symptoms usually result from bone marrow suppression and infiltration of other organs and tissues by leukemic cells. Weakness, fever, headache, generalized swelling of lymph nodes, petechiae or hemorrhage in skin and mucus membrane are seen. There is also bone pain and tenderness, resulting from marrow expansion, with infiltration of subperiosteum. Central nervous manifestations such as headache, vomiting,

nerve palsies resulting from meningeal spread which are more common in children than in adults; and more common in ALL than AML.

- **Signs**—the clinical features are due to anemia and thrombocytopenia viz pallor, dyspnea, fatigue, petechiae, ecchymosis, epistaxis and melena. Hepatosplenomegaly is present in later stages. There is an increased susceptibility to infection. Cervical lymphadenopathy, secondary to pharyngeal sepsis is seen. Intracranial and subarachnoid hemorrhage may result from thrombocytopenia and leukostasis (intravascular clumping of leukemic blasts in the small blood vessels of brain). There is recurrent infection of lungs, urinary tract skin, mouth, rectum and upper respiratory tract, which may result in fever.
- **Chloroma**—localized tumors consisting of leukemic cells are called chloromas, surface of which turn green when exposed to light because of the presence of myeloperoxidase.

Oral Manifestations

- **Lymph nodes**—the submental, cervical and pre- and post-auricular lymph nodes may be enlarged and tender.
- **Symptoms**—paresthesia of lower lip and chin may be present. There may be toothache due to leukemic cell infiltration of dental pulp.
- **Signs**—the oral mucous membrane shows pallor, ulceration with necrosis (**Fig. 16-48**), petechiae, ecchymosis and bleeding tendency. There may be massive necrosis of lingual mucosa with sloughing.
- **Gingiva**—gingiva shows hypertrophy (**Fig. 16-49**) and cyanotic discoloration. The hypertrophy may be due to leukemic cell infiltration within gingiva or due to local irritants. The gingiva appears boggy, edematous and deep red bleed easily due to ulceration of sulcus epithelium and necrosis of underlying tissue.

Fig. 16-48: Ulceration seen in palate in posterior area in leukemia patient (Courtesy Dr Bhaskar Patle).

- **Teeth**—mobility of permanent teeth may be present.
- **Lip**—in some cases crusting of lip can be seen (**Fig. 16-50**).
- **Infection**—oral infections (candidial, viral and bacterial) are serious and potentially fatal complications in leukemic patients.

Fig. 16-49: Hypertrophy seen in gingiva (Courtesy Dr Milind Chandurkar).

Fig. 16-50: Crusting of lip seen in leukemia.

Diagnosis

- **Clinical diagnosis**—gingival hypertrophy with symptoms of anemia and thrombocytopenia may suspect the leukemia.
- **Laboratory diagnosis**—the total WBC count may vary from a very low count less than 1×10^6 per cu mm to as high as 5000×10^6 per cu mm or more. The peripheral smear shows significant number of immature granulocytes or lymphatic precursors or even stem cells. Bone marrow is hypercellular with replacement of normal marrow elements by leukemic blast cells in varying degree. There may be an associated normochromic anemia, thrombocytopenia and decrease in normal functioning neutrophils count.

Table 16-3: Summary of drugs commonly used in treatment of leukemia

Phase	Lymphoblastic	Myeloid
Induction	Vincristine (IV) Prednisone (oral) A-asparaginase (IV) Daunorubicin (IV) Methotrexate (intrathecal)	Daunorubicin (IV) Cytosine arabinoside (IV) Etoposide (IV) Thioguanine (oral)
Consolidation	Daunorubicin (IV) Cytosine arabinoside (IV) Etoposide (IV)	Cytosine arabinoside (IV) Amsacrine (IV) Mitozantrone (IV)
Maintenance	Prednisone (oral) Vincristine (IV) Mercaptopurine (oral) Methotrexate (oral)	

Management (Table 16-3)

- *Phase of induction*—it is treated using combination of vincristine (1.4 mg/m² every week of 1 month), L-asparaginase (600 units/m² biweekly for 1 month) and prednisone (40 mg/m² orally daily for 1 month). As the leukemic cells regress, regrowth of normal cells occurs and the patient goes rapidly into remission. Acute non-lymphoblastic leukemia is treated with daunorubicin, cytarabine and 6-thioguanine. All these drugs are very toxic to the normal as well as leukemic cells and therefore, treatment is given in pulses to reduce toxicity.
- *Phase of consolidation*—in it, drugs used are daunorubicin, mercaptopurine, cytarabine and methotrexate with intrathecal therapy using the last two drugs, together with irradiation of the cranium to eradicate the disease from central nervous system. Radiation reduces the risk of relapse in central nervous system when given with methotrexate.
- *Phase of maintenance*—in this phase, patient receives a repeating cycle of above drugs until two or three years have been completed. This therapy requires lower dose of chemotherapeutic drugs.
- *Transplantation*—allogenic bone marrow transplantation from HLA identical twin is done. Ablative therapy has been utilized to eradicate the patient's residual leukemic cells and normal cells with intensive irradiation and chemotherapy. After this, reconstruction of the hemopoietic tissue is done with precursor cells from the donor.
- *Allopurinol*—catabolic products of leukemic cells produce uric acid and cause hyperuricemia, which is prevented by allopurinol.
- *Supportive therapy*—transfusion of red cells and platelets may be required in cases of severe anemia and thrombocytopenia. Combination of higher antibiotics like aminoglycosides with cephalosporin, allopurinol, before starting anti-leukemic agents are given to prevent hyperuricemia.

- *Topical treatment for gingival bleeding*—to stop gingival bleeding, remove obvious local irritants by scaling and direct pressure is applied by use of absorbable gelatin or collagen sponge topical thrombin.
- *Management of oral ulcers*—it includes topical antibacterial with povidone iodine solution, chlorhexidine rinses or tetracycline rinses.
- *Psychological support*—it is very important as delusion, hallucinations and paranoia are not uncommon during periods of severe bone marrow failure.

Chronic Myeloid Leukemia

Chronic leukemia is characterized by the presence of large leukemic cells and differentiated WBCs in the bone marrow, peripheral blood and other tissues. It has a prolonged clinical course even without therapy.

It is associated with the presence of a distinctive chromosomal abnormality, i.e. Philadelphia chromosome.

Clinical Features

- *Age*—the disease occurs chiefly between the age of 35 and 60 years.
- *Onset*—the disease may be discovered during routine examination, when splenomegaly or an elevated count is noted.
- *Symptoms*—there may be slowly advancing anemia with loss of weight, prominence of abdomen and discomfort in the left upper quadrant due to splenomegaly. Attacks of acute left upper abdominal pain may develop due to infarction of spleen. Anemia causes weakness, fatigue and dyspnea on exertion.
- *Sign*—as the disease progress, thrombocytopenia can cause petechiae, ecchymosis as well as hemorrhage from the skin and mucous membrane. Liver may be enlarged but lymph nodes are normal.

Diagnosis

- *Clinical diagnosis*—not so specific
- *Laboratory diagnosis*—examination of blood shows a normocytic and normochromic anemia. WBC count is considerably increased and may be between 50×10^6 to 500×10^6 cells per cu mm. Peripheral smear shows mature leucocytes (**Fig. 16-51**) but, few immature forms may also be present. The platelet count is often high initially but with treatment, it comes down.

Management

- *Chemotherapy*—the treatment of choice is chemotherapy using the drug busulphan given orally in a dose of 4 mg daily or in large doses of 50-100 mg spaced 2 to 3 weeks

Fig. 16-51: Chronic myeloid leukemia showing mature leukocytes.

apart. The treatment is continued for 12 to 18 weeks and should be discontinued when WBC count is between 10×10^6 and 20×10^6 /cu-mm, otherwise busulphan may cause aplasia of the bone marrow.

- *A combination chemotherapy* using a small dose of busulphan 2 mg daily along with mercaptopurine 50 mg daily or thioguanine 80 mg daily.
- *Other therapy*—radiotherapy and splenectomy are other treatment of choice.

Chronic Lymphatic Leukemia

It is a slowly progressing malignancy involving lymphocytes. It is characterized by the accumulation of long lived, non-functional B lymphocytes.

Clinical Features

- *Age and sex*—it occurs more frequently in males and majority of the patients are over 45 years.
- *Onset*—the onset is very insidious.
- *Symptoms*—tiredness and ill health are common, although some patients are symptom free and the disorder is found incidentally. Bone marrow infiltration causes anemia and thrombocytopenia and results in pallor, weakness, dyspnea and purpura.
- *Signs*—there is a moderate enlargement of lymph nodes which are firm, rubbery and discrete. Liver and spleen are usually enlarged and palpable. There is an increased susceptibility to infection as the leukemic B cells are non-functional. Leukemic infiltration results in skin nodules, intestinal malabsorption, pulmonary obstruction or compression of the central or peripheral nervous system.
- *Lymph nodes*—the most common groups of lymph nodes involved are cervical, axillary and inguinal group.

Clinical Staging

- *Stage A*—Lymphocytosis is less than three areas of lymphoid enlargement, no anemia or thrombocytopenia.

- *Stage B*—more than three areas of lymphoid enlargement, no anemia or thrombocytopenia.
- *Stage C*—anemia or thrombocytopenia, regardless of number of area of lymphoid enlargement.

Oral Manifestations

- *Gingiva*—the most common oral finding is hypertrophy of gingiva. There may be ulceration with necrosis and gangrenous degeneration; a dark brown exudate and foul fetor oris are present.
- *Tongue*—the tongue is frequently swollen and dark.
- *Lymph nodes*—there is regional lymphadenopathy.
- *Teeth*—rapid loosening of teeth due to necrosis of periodontal ligament has been reported. Destruction of alveolar bone also occurs in some cases.

Diagnosis

- *Clinical diagnosis*—signs of anemia and thrombocytopenia with gingival hypertrophy and insidious onset may give clue to the diagnosis.
- *Laboratory diagnosis*—peripheral blood smear shows mild anemia and a large number of small lymphocytes. Lymphoblasts are rare but increase in the terminal stages of disease. WBC count may increase up to 1000×10^6 per cu mm.

Management

- *Supportive treatment*—general measure to maintain good health; adequate rest, good food and exercise should be advised.
- *Chemotherapy*—chlorambucil 6-10 mg/day for 14 days with break of 14 days and cyclophosphamide 2-3 mg/kg IV for 6 days.
- *Combination therapy*—cyclophosphamide doxorubicin, vincristine and prednisone have been recommended.
- *Radiotherapy*—it is useful for large granular masses, if they cause symptoms. Radiotherapy with very small doses, of only 150 rads over a period of five weeks, is very effective and may induce satisfactory remission.
- *Steroids*—if the bone marrow is severely involved, initial treatment with prednisone 40 mg daily and 25-50 mg daily later should be given.

Radiographic Features of Leukemia

- *Site*—it affects the entire body as it is malignancy of bone marrow.
- *Margins*—it is presented as ill defined patchy radiolucent area. This patchy area may coalesce to form larger areas of ill defined radiolucent regions.
- *Chloroma*—foci of leukemic cells may present as a mass which may behave like a localized malignant tumor. It is called as Chloroma.

- *Moth eaten appearance*—destruction of alveolar bone is the most common manifestation of leukemia. Bone loss may be in the form of transverse lines of increased radiolucency or irregular areas and bone loss produced the so called, moth eaten appearance.
- *Sclerosis*—sclerosis of bone may be presented alone or in combination with destructive.
- *Onion peel appearance*—there is formation of bone beneath the periosteum. The new bone takes the form of a thin white line parallel with the shaft of the bone and sometimes separated from it by a thin dark line (onion peel appearance).
- *Skull*—it is rarely involved and it may reveal areas of bone destruction.
- *Teeth*—the developing teeth may be displaced from their normal position.
- *Lamina dura*—there is also loss of lamina dura with loosening of teeth.
- *Jaw bone*—generalized bone loss may be seen.

Differential Diagnosis

- *Metabolic disorders*—some of the metabolic disorders can cause generalized rarefaction of the jaw. But these can be excluded on the basis of blood picture.
- *Lymphoma*—clinical picture and blood testing should be done to rule out leukemia.

Variant of Leukemia

- *Hairy leukemia*—it is a variant of chronic lymphatic leukemia in which there is splenomegaly, severe neutropenia, monocytopenia and the characteristic appearance of hairy cells in blood and bone marrow. These hairy cells appear to be a cross between the lymphocytes and monocytes. It occurs mainly in adults and show male predilection. Manifestations result from infiltration of bone marrow, liver and spleen. Splenomegaly is massive and hepatomegaly is less common. Hairy cell can be identified on the peripheral smear.
- *Prolymphocytic leukemia*—it is another variant of chronic lymphatic leukemia in which there is massive splenomegaly with little lymphadenopathy and a very high WBC count. The characteristic cell is a large lymphocyte with prominent nucleus.
- *Aleukemic leukemia*—it is the sub-leukemic form of leukemia in which the WBC count of the peripheral blood is normal or even subnormal and abnormal or immature leucocytes may be present.

Dental Considerations

- *Topical treatment*—to stop gingival bleeding, removal of local irritants, direct pressure and use of absorbable

gelatin, collagen sponge, topical thrombin and placement of microfibrillar collagen are carried out.

- *Platelet transfusion*—if these local measures are not successful, platelet transfusion is given.
- *Predental treatment consideration*—platelet transfusion and intravenous combination of antibiotics are required before any dental treatment.

Myeloma

Multiple Myeloma

It is also called as '*myelomatosis*'. It is a malignant neoplasm of plasma cells of the bone marrow with widespread involvement of the skeletal system, including the skull and jaws. It is thought to be multicentric in origin.

Origin

- *Proliferation of single clone*—normal plasma cells are derived from B-cells and produce immunoglobulin, which contain heavy and light chain. In myeloma, plasma cells produce immunoglobulin of single heavy and light chain, a monoclonal protein commonly referred as para-protein. There is proliferation of a single clone of abnormal plasma cells in the bone marrow.
- *Bence Jones proteinuria*—in some cases, only light chains are produced and these appear in urine as Bence Jones proteinuria.

Clinical Features

- *Age and sex*—the most common age group affected is between 40 and 70 years with male to female ratio 4:1.
- *Site*—usually the skull, clavicle, vertebrae, ribs, pelvis, femur and jaws are involved.
- *Symptoms*—skeletal pain associated with motion or pressure over the tumor masses, is an early symptom. Pain in the involved bone may be aggregated by an exercise and relieved by rest. Patient may complain of vomiting due to increase in the serum calcium level.
- *Pathological fracture*—spontaneous pathological fracture can also occur.
- *Bleeding tendency*—patient may have bleeding tendency and bruising of skin due to anemia and thrombocytopenia. The cause of bleeding is that the abnormal globulins bind with coagulation factors which also increase the viscosity of blood.
- *Sign*—swelling over the areas of bone involvement may be detectable. There is an increased susceptibility to infection due to abnormal immunoglobulin production by the plasma cells.
- *Hypercalcemia*—mobilization of calcium from the skeleton may cause hypercalcemia resulting in

nephrocalcinosis, lethargy, drowsiness and eventually coma, if untreated.

- **Complication**—the common cause of death is renal failure, caused by accumulation of abnormal proteins in the renal tissue.

Oral Manifestations

- **Site**—mandible is more commonly involved than the maxilla and particularly angle of the mandible, because of its greater content of marrow. Lesions have also been reported in temporomandibular joints.
- **Symptoms**—the patient may experience pain, swelling and numbness of the jaw. Epulis formation or unexplained mobility of teeth is also detectable.
- **Signs**—intraoral swelling tends to be ulcerated, rounded and bluish red similar to a peripheral giant cell lesion. Sometimes, swelling may erode buccal plate and produce rubbery expansion of jaw. Chronic trauma produces an inflamed and ulcerative necrotic surface. On palpation, swelling is tender and eggshell cracking may be elicited.
- **Signs of bone marrow involvement**—secondary signs of bone marrow involvement such as pallor of oral tissue, intraoral hemorrhage and susceptibility to infection may also be seen.
- **Hemorrhage**—excessive hemorrhage may be caused by thrombocytopenia, secondary to increased proliferation of the plasma cells in marrow.
- **Oral amyloidosis**—it is a complication of this disease. The tongue may be enlarged and studded with small garnet-colored enlargements, including nodes on lip and cheeks. Tongue enlargement may cause impairment of speech, mastication and deglutition. Amyloid can also deposit in the gingivae, where it can cause soreness and inability to wear dentures.
- **Oral hairy leukoplakia and candidiasis**—this can be present in rare cases of multiple myeloma as myeloma is also immunosuppressive disease.

Radiographic Features

- **Sites**—they are usually bilateral and may become confluent forming a larger area of destruction. It is seen in mandibular posterior region and ramus.
- **Punched out lesion**—in the radiograph (**Fig. 16-52**), it appears as a small rounded and discrete radiolucency having punched out appearance. There may be numerous areas of bone destruction within the region of generalized radiolucency. Diffuse destructive lesions of bone may occur.
- **Shape**—some lesions have oval and cystic shape.
- **Margins**—it has well defined margins and lack the circumferential osteosclerotic activity. In some cases,

Fig. 16-52: Punched out lesion seen in skull of patient of multiple myeloma (Courtesy Dr Ganju).

borders of the lesion may display a thin sclerotic rim and even areas of opacification.

- **Size**—the lesions may vary in size from few millimeters to centimeters, or more in diameter.
- **Soft tissue lesions**—soft tissue lesions have been reported in jaws and nasopharynx, which appear on radiograph as smooth bordered soft tissue masses, possibly with underlying bone destruction.
- **Teeth**—if good deal of mineral is lost, the teeth may appear to be too opaque and may stand out conspicuously from their osteopenic background.
- **Lamina dura**—lamina dura and follicle of impacted teeth may loose their typical corticated surrounding bone in a manner analogous to that seen in hyperparathyroidism.
- **Cortical border**—mandibular lesion may cause thinning of cortical lower border or endosteal scalloping.

Diagnosis

- **Clinical diagnosis**—skeletal pain with oral amyloidosis with bleeding tendency may give clue to the diagnosis.
- **Radiological features**—punched out lesion in the skull is typical of multiple myeloma.
- **Laboratory diagnosis**—plasma cells are round or ovoid cells with eccentrically placed nuclei exhibiting chromatin clumping in 'cartwheel' or 'checkerboard' pattern. Russell bodies are common finding in multiple myeloma. *Bence Jones proteins*, which coagulate when the urine is heated at 40 degree Celsius, can be demonstrated in the urine of patients suffering from multiple myeloma.

Differential Diagnosis

- *Metastatic carcinoma*—multiple myeloma is, comparatively, more common than metastatic carcinoma. The absence of definitive serum, characteristic history of treatment for an earlier tumor indicates that the disease is metastatic carcinoma.
- *Histiocytosis X*—the incidence of Histiocytosis X is most common in children. The lesions of this disease have ragged and vague margins.
- *Cherubism*—multiple radiolucent lesions of cherubism may be scattered throughout the jaws, commonly seen in the first or second decades of life. Radiolucent lesions may be multilocular or unilocular, elliptical without well circumscribed or hyperostotic borders.
- *Advanced osteomyelitis*—shows the presence of visible cause.
- *Simple bone cyst*—it may be bilateral but they are usually corticated in part and characteristically interdigitate between roots of teeth in much younger population.

Management

- *Chemotherapeutic agents*—general disease is treated with chemotherapeutic agents like melphalan and cyclophosphamide.
- *Management of anemia and hypercalcemia*—patients who present with anemia, hypercalcemia, and evidence of renal damage require urgent management with alkalization of urine with oral bicarbonates, high fluid intake, corticosteroids and possibly mithramycin to reduce calcium level.
- *Blood transfusion*—it may be required if hemoglobin is less than 10 gm/dl.
- *Cell transplantation*—stem cell autotransplant may improve quality of life and prolong survival.
- *Radiotherapy*—this is effective for localized pain not responding to simple analgesics and for pathological fractures.
- *Bi-phosphonate therapy*—it may reduce bone pain and skeletal events.
- *Others drugs*—alpha interferons may prolong the plateau phase. Inorganic fluoride phosphate to reduce bone pain.

Solitary Myeloma

It can appear in any bone and remains for long period of time. It usually involves single bone. The hematological and biochemical changes seen in multiple myeloma are not seen in solitary myeloma. Patient is not anemic and serum protein level is normal. Others symptoms are same as in multiple myeloma.

Plasmacytoma

Plasmacytoma is unifocal, monoclonal and neoplastic proliferation of plasma cell arising within the bone. Extramedullary location without bony involvement may occur in the nasopharynx, nasal cavity, paranasal sinuses and rarely in the oral cavity. It is also called as '*plasma cell myeloma*'. It is least aggressive part of plasma cells neoplasm.

Clinical Features

- *Age and sex*—mean age of occurrence is in age of 51 years and males are affected more commonly than females.
- *Site*—nares, tonsil, palate tongue, gingivae and the floor of mouth. They are also found in pleura, mediastinum, thyroid, ovary, intestine, kidney and skin.
- *Symptoms*—pain and swelling are the most common complaints.
- *Signs*—pathologic fractures are common.
- *Metastasis*—regional metastasis may develop in small number of cases.

Oral Manifestations

- *Site*—it is rare in jaws and can occur in mandible or maxilla.
- *Appearance*—the lesions are described as sessile or polypoid reddish masses in mucous membranes, which become lobulated as they enlarge but exhibits the tendency to ulcerate.
- *Symptoms*—pain is not prominent symptom unless bone is invaded.
- *Signs*—there may be bleeding and ulceration of oral mucosa.

Radiographic Features

- *Forms*—it mainly occurs in two forms, one is purely destructive lesion suggestive of metastatic carcinoma and the other type is an expansible lesion, suggestive of a giant cell tumor.
- *Destructive lesion*—there is no new bone at the margins or under the periosteum. The margins are clearly defined or show evidence of infiltration. In the flat bone, solitary myeloma extends along the bone and produce a saucer-shaped lesion, with undulating margins.
- *Expansible lesion*—an area of bone destruction is well demarcated from the surrounding bone and sometimes is corticated. If the bone is expanded, subperiosteal new bone may form a complete bony covering of the tumor. In the substance of the lesion, trabeculae vary considerably in number and thickness. Some are thin and delicate, while others are coarse.

Diagnosis

- *Clinical diagnosis*—it is more or less mimicking multiple myelomas.
- *Radiological features*—destructive lesions are seen in jaws.
- *Laboratory diagnosis*—it contains densely packed plasma cells and is indistinguishable from the bony lesion in multiple myeloma. There may be considerable nuclear and cellular pleomorphism. Russell's bodies can also be found. It is similar to multiple myeloma. Bence Jones proteins are found in urine. There is also hyperglobulinemia and anemia.

Management

- *Radiotherapy*—radiotherapy at dose of 4000 cGy is given.
- *Surgical excision*—in some cases, conservative surgical excision should be carried out.

Malignant Tumors of Salivary Gland

It is described in Chapter 26: Salivary Gland Disorders.

Treatment Modalities of Oral Cancer

Oral cancer is treated by surgery, radiotherapy and chemotherapy or by combination of these. The other developing techniques in the treatment of oral cancer are laser therapy, hormonal therapy, hyperthermia, etc.

Following histological confirmation of oral cancer, each patient should undergo a thorough assessment. First, the extent of the malignant disease should be accurately delineated and also, the fitness of the patient to undergo treatment is determined. Many patients afflicted by this disease are elderly; such patients likely to be suffer from other chronic illness and also are at risk of having malignant diseases of respiratory or digestive tract.

The oral lesion is carefully examined and the details are recorded. Photography is of great value in assessing the response of the lesion to treatment. The degree of involvement of adjacent structures by tumor can be assessed by palpation.

Radiotherapy

Advantage of Radiotherapy

- *Avoiding surgical procedure*—due to radiotherapy, major surgical procedure is avoided.
- *No cosmetic and functional defect*—as surgery is avoided, there is no cosmetic or functional defect.
- *Management of early metastasis*—early metastatic spread to cervical lymph nodes can be treated.

- *Management of multiple lesion*—multiple malignant lesions at different anatomic sites can be treated at the same time.

Disadvantages

- *Osteoradionecrosis*—there is risk of post-irradiation osteoradionecrosis.
- *Effect on normal tissue*—there is harmful effect on soft tissue and salivary glands.
- *Retreatment not possible*—in case of failure or recurrence, re-treatment with radiation is not very successful.

Indications

- *Vascularized lesion*—it is indicated in early well vascularized lesion.
- *Cervical lymph nodes*—elective irradiation of the cervical lymph nodes.
- *Post-surgical*—to destroy malignant cells peripheral to a large lesion after surgical procedure.
- *Palliative treatment*—palliative radiotherapy for a large lesion, which is not surgical irradiation.

Types of Beams

Electron Beam

X-ray is produced in an X-ray machine first by accelerating electron and then making them strike a target. This causes the electron to loose energy in the form of X-ray photon which is directed towards the patient, for either diagnostic or therapeutic purpose.

The energy of the photon is proportional to the energy of the electron from which they were produced which in turn is dependent on the speed with which electrons were travelling before they struck the target.

Proton Beam

Protons are much heavier than electrons and have a positive charge. They have a finite range like electrons but at the end of their range, Bragg's peak occurs where they deliver the maximum dose.

Protons have virtually no side scatter which adds to the therapeutic ratio. By appropriately adjusting the proton beam, Bragg's peak can be positioned with the tumor almost anywhere in the body, sparing the normal tissues; both proximal and distal to the tumor.

Neutron Beam

Cancer cells that are hypoxic or that are in certain stages of the cell cycle or that are proficient at repairing damage are relatively resistant to be killed by photon or electron beam irradiation.

It was found in the laboratory that such cells are less resistant to be killed by neutron beam because neutrons produce much denser ionization in tissues, inflicting a relatively greater injury to malignant tissues than the healthy tissues, as compared with photon and electron irradiation.

Radiotherapy Technique, Planning and Equipment

There are three major modalities of radiation therapy—external beam radiation or teletherapy, brachytherapy and radioactive isotopes.

Teletherapy

This is the most common modality of radiation therapy. The X-rays of different energies are used for diagnostic and therapeutic purposes.

Superficial X-ray

These rays have energy between 50 Kilo Voltage (KV) to 140 KV with a limited range of penetration. The tissues deeper than 5 cm receive less than 20% of the dose. Thus, this can treat only superficial skin lesions. The absorption of superficial X-rays is by the photoelectric effect.

The superficial X-rays are used to treat the skin lesions of limited thickness, often with a lead cutout to delineate the field. Only direct field is used with a filter of aluminum to decrease the amount of very low energy X-rays. The quality of X-rays used depends on the maximum energy and filtration used.

Orthovoltage X-ray

These X-rays have energies between 250 KV to 350 KV and these are used as most common treatment modalities. The tissue penetration at 5 cm in depth is about 60%. The maximum absorbed dose from single field is at the skin surface and the deeper tissues are treated by using multiple therapies. Orthovoltage radiations are still used for palliative therapy where poor tissue penetration is of little importance.

Cobalt 60 Unit (Fig. 16-53)

This unit has a cobalt source surrounded by a protective shielding with a shutter system which allows the patient to be treated through an adjustable collimator. The source produced gamma rays of 1.17 MeV to 1.33 MeV which behave exactly like X-rays and have a decay half life of 5.27 years. Hence, the treatment times have to be adjusted monthly. Source, diameter is about 2 cm, which is larger than a linear accelerator target, so the cobalt beam has a large penumbra. The maximum depth at which dose delivered is 5 cm beneath the skin, with 55% of dose

delivered at 10 cm. The disadvantages compared to linear accelerator are decreased tissue penetration and less skin sparing and wider penumbra.

Fig. 16-53: Cobalt 60 unit used to give radiotherapy

Megavoltage

It includes linear accelerators (Fig. 16-54) and betatrons. These machines accelerate electrons across millions of volts to provide a continuous X-ray spectrum, with the maximum energy equal to the accelerating X-ray. These machines normally operate at 4-8 MeV range and spare the skin.

The target in linear accelerator is small, which produces a narrow penumbra compared to that of the cobalt unit. It is more expensive to maintain (than the cobalt unit) and requires staff trained in physics, as it requires daily calibration. It produces high energy beams with good tissue penetration. The energy from these high energy beams is absorbed by Compton Effect. The energy absorption is not dependent on the average weight of the tissues. So, the bones, cartilage and soft tissues receive the same dose and

Fig. 16-54: Linear accelerator used in radiotherapy unit.

thus, reduce the chances of necrosis. Higher the energy of X-ray, greater is the degree of skin sparing and tissue penetration.

Advantages of megavoltage over orthovoltage therapy

- *Less chances of osteoradionecrosis*—orthovoltage irradiation is preferentially absorbed in bones that is why bone stand out from soft tissues on the diagnostic X-ray picture. After irradiation, healthy bone receives a higher dose of radiation than the tumor itself. Therefore chances of osteoradionecrosis of mandible is relatively common with orthovoltage treatment and in megavoltage irradiation dose to bone is no higher than the dose to the tumor and the incidence of osteoradionecrosis is decreased dramatically.
- *Skin sparing*—super voltage photon deposits their maximum dose deeper in the body than the skin while orthovoltage photon deposits maximum dose in the superficial surface of the skin. Higher the energy of super voltage photon, deeper will be the region of maximum dose and this is called as skin sparing and hence the skin reactions are very much less severe with super voltage irradiation.
- *Sharper penumbra*—when the photons enter the body, they interact with atoms which make them scatter. Orthovoltage photons often scatter sideways which means they tend to get out of the line of radiation beam and then end up irradiating adjacent healthy tissues. In megavoltage therapy, there is minimum scattering of photons sideways thus sparing the adjacent tissues. This is important in treating the tumor situated near the eyes and brainstem.

Electrons (4-20 MeV)

Photons have no electrical charge hence they deposit dose in tissue at an exponential rate, which means that tissue beyond the tumor also gets significant irradiation. Electron has a negative charge. A charged particle deposits uniform dose for a certain distance and then virtually none, which means that the tissue behind the tumor gets little irradiation. Thus, the electron beam is better suited than photon beam for treating a tumor located on or just under the skin such as basal cell carcinoma or in metastases to cervical lymph nodes.

High energy photons can deliver a relatively low dose to the healthy tissue proximal to the tumor, while electrons deliver a low dose to the distal tissue. In many situations combining the two can provide the patient with the best dose distribution.

Linear accelerator or betatrons can produce a therapeutic electron beam by allowing the electron to pass through a scattering foil rather than striking a target with X-ray production.

Field Arrangement

Single Field Arrangement

In this, tumor is treated with one field only. These treatments are palliative because of quick and easily reproducible therapy. If the maximum applied dose is to be at the skin surface, wax build up is required. The isodose lines can be corrected by a tissue compensator; the simple compensator is called as a *wedge compensator*, which is a high density metal in the shape of a wedge. Wedge shifts the isodose by decreasing the transmission of X-ray beam with increasing thickness of wedge.

Parallel Opposed Fields

It is the next simple field arrangement where the two parallel fields are opposite to one another. This produces a fairly even distribution throughout the irradiated area.

Wedge Lateral Field

Two right angled fields can be combined to irradiate a discrete tumor volume rather than placing them parallel. The equal distribution is achieved by the use of a field wedge.

Multiple Field

Head and neck tumors are superficial and can be irradiated by two fields, without compromising the depth, while tumors of thorax and abdomen require 3 to 4 fields to achieve an adequate concentrated tumor dose.

Most common form of multiple field treatment is with 4 fields, arranged two parallel and two opposed pairs (4 field brick technique)) which produce good tumor localization with a square volume.

Rotational and Arc Therapy

These are moving field techniques which are modifications of multiple field therapy. In rotational therapy, the radiation source rotates around the tumor isocentrically to provide an even dose throughout the tumor volume with a dose decreasing toward the periphery; this produces excellent tumor localization but all tissues are included in the primary beam. So to spare a selected normal tissue from the primary beam, only part of a rotation (arc therapy) is made.

In arc therapy, wedges are usually required and they may need reversing during treatment, such therapy is time consuming and less frequently used. With the advent of high energy X-ray machines which are able to provide a good dose distribution with 3 to 4 fields, use of arc therapy has declined.

Radiotherapy Planning

The following factors should be considered while planning for radiotherapy:

Patient Positioning and Immobilization

Before planning radiotherapy, patient's position should be chosen which depends on many factors such as treatment machine, general condition of the patient and whether the treatment is radicular or palliative. Radiotherapy can be delivered in supine, prone or even sitting position.

The sitting position is useful in the palliative treatment of bronchial tumors, where a patient is unable to lie flat due to pain. Although the sitting position is well tolerated, better immobilization accuracy and reproducibility are achieved in supine position or prone position. Ideally, the patient should remain in the same position for all fields, with the same support and immobilization device so that the treatment is easily reproduced.

The planning couch must resemble the treatment couch in every way as the patient contour changes on different surfaces. The planning couch must also have the same immobilization as the therapy machine, which normally consists of a range of head rest, arm rest and mouth bites.

Immobilization of the patient of head and neck tumor is essential as high dose must be given accurately to a small volume avoiding the adjacent radiosensitive organs such as brainstem, eye and cervical cord.

A thin transparent plastic shell is used which can be molded to the patient's skin following the surface contour. The field size, entry and exit point, can be redrawn on the shell rather than the patient's skin. The shell usually helps to maintain the patient position during the treatment with the maximum support and comfort.

Simulation and Beam Verification

A simulator is an isocentrally mounted diagnostic X-ray unit that mimics the geometrical arrangement of any therapy machine. A simulator couch is identical to the therapy couch so that the patient maintains the same position.

The patient is placed on the couch in the treatment position and the anterior and posterior field are aligned. This is done either clinically or with the help of fluoroscopic screening facility, using a skeletal reference point. Contrast media and metallic markers can be used to identify the skin and other soft tissues.

The tumor volume is localized in the coronal plane and a verification X-ray is taken. A radiopaque ruler or ring is introduced to calculate the magnification. For single and parallel opposed fields, this is sufficient and the field can

be marked on the patient's skin or shell. Where a tumor volume is required, a lateral film is taken through the treatment plane which determines the anterior and posterior limits in the sagittal plane.

Tumor Volume

After the field position has been verified an outline of the patient is taken through the center of the volume by applying a pliable lead strip to the patient. This outline is then transferred to a paper, with the field in center, the patient in the midline of the couch surface and often a reference point marked.

The tumor volume is calculated from orthogonal X-ray films and put onto the transverse outline through the tumor center. The coronal projections of tumor volume are normally obtained from the anteroposterior films. The lateral check films are used to calculate the sagittal tumor volume. Tumor volume depends on several factors, one of which is the experience and philosophy of the radiotherapist.

Isodose Distribution

A treatment plan is a result of the addition of Isodose curves of the entire field. This will produce an even dose across the tumor volume with less than 5% variation. The dose of surrounding tissues should be as small as possible.

Brachytherapy

In brachytherapy or intracavitary radiation therapy, the radioactive source is close to the patient's body as it is contained in a custom fabricated carrier device and placed directly on the surface of the tumor. Brachytherapy is divided into three types:

Mould Treatment

The radiation source is placed into a plastic mould on the patient's skin or mucous membrane to treat superficial tumors. Most common sources are iridium-192, cobalt-60, caesium-137 and gold-198. The radiation dose from the mould falls off rapidly obeying an inverse square law so that the treatment depth is limited. Deep lesions cannot be treated by this method.

Interstitial Therapy

It involves the insertion of a radioactive source into the tumor.

Intracavitary Therapy

In it, radiation source is placed into the body cavity to irradiate the surrounding tissues. The dose from the source

obeys the inverse square law, so that the dose distribution falls off rapidly.

Radioactive Isotopes

This form of treatment involves the radioactive isotopes that are not confined in a protective container. The useful therapeutic effects can be obtained if the target organ concentrates the isotopes and increases its specific dose. The dose can be made to remain in the body cavitations by chelating them to high molecular weight colloids; the colloids will remain in the body cavity and deliver a high surface dose with little penetration.

Iodine-131 (^{131}I)

It is concentrated in thyroid follicular cells which can be killed by I^{131} hence, it is useful in the treatment of thyrotoxicosis and follicular adenocarcinoma. Physical half life is 8 days but the biological half life is only 3 days. Iodine-131 is given orally and the maximum dose is limited to 200 mCi.

If the patient contains more than 30 mCi of I^{131} , he should be confined in an isolated room and the public contact is allowed only when they got less than 15 mCi of I^{131} , as iodine is excreted in all body fluids. Precaution such as special toilet facilities should be taken.

Phosphorus-32 (^{32}P)

It is taken up by bone so, it can be used in the treatment of polycythemia vera. These isotopes are pure beta emitters and are not excreted readily in body fluids. Radioprotection is much easier and doses above 10 mCi are rarely necessary.

Yttrium-90 (^{90}Y)

The isotopes are pure beta emitter and are available as silicate colloid. It can be injected into the body cavity to palliate malignant effusion. The surface dose is high but falls to 50% at 1 mm depth.

Factors that Influence the Dose Required for Tumor Control

Histology of Malignant Cell

The tumors originating from the cell which are sensitive to radiation are easy to cure while those originating from those cells which are resistant or less sensitive to radiation are difficult to cure, e.g. lymphoma is easier to cure than carcinoma which in turn is easier to cure than osteogenic sarcoma.

Primary Site of the Tumor

If the tumor is located in the tissues which are in close proximity with glottis, brainstem or spinal cord, it becomes difficult to treat such tumors as these tissues get the same exposure to radiation therapy inviting complications. If the tumor is in the region of rich lymphatic drainage, it is difficult to treat and vice versa.

Size of the Tumor

Larger the tumor, higher the dose required to control it. It may be due to ratio between the number of cancer cells (tumor burden) requiring sterilization and the number of ionizing particles (dose) available to destroy them. The treatment depends on the tumor burden, number of hypoxic foci in the tumor and heterogeneity of the tumor. Larger tumors have more hypoxic foci than smaller ones. As the size of the tumor increases, it undergoes more mutation and the tumor becomes increasingly heterogeneous, which also requires to increase the dose for tumor control.

Strategies for Improving the Therapeutic Ratio

The ideal machine for radiotherapy should be that, which deliver a lethal dose to all malignant cells, but without any dose to healthy cells does not yet exist. Therefore, a number of strategies have been developed or are being investigated in an effort to obtain a favorable therapeutic ratio. They are as follows:

Altering the Degree of Radiation Injury

Effort has been made to increase the degree of injury to malignant cells that produced by a given dose of irradiation. The technique for this includes—

Hyperthermia: It selectively injures to two kinds of cells that are most resistant to irradiation, hypoxic cells and cells in the late 'S' phase of the cell cycle. In treating tumors in human beings, eliminating these cold and hot spots has been a major problem. Radiofrequency, microwaves and ultrasound are all being tried for heating human tumor and the technology is rapidly developing.

Hyperbaric oxygen therapy: The most important modifier of the biologic effect of ionizing radiation is molecular oxygen. Oxygen affects the initial chemical product of radiation interaction with biologic material. The important free radicals have shorter half lives and these are very reactive molecules.

It has been shown, from various studies, that oxygen enhancement ratio, i.e. the ratio of dose required for equivalent cell killing, in absence of oxygen, compared with

presence of oxygen ranges from about 2.5 to 3.5 for given survival rate. Three times as much radiation is required under hypoxic conditions than under conditions when oxygen is present.

Neutron therapy: Cancer cells that are hypoxic in certain stages of cell cycle are proficient at repairing damage and relatively resistant to be killed by photons and electron beam irradiation. These cells are resistant to neutron beam because neutrons produce much denser ionization in tissues. So, neutron irradiation inflicts greater injury to malignant tissues than healthy tissues, when compared with photon or electron irradiation.

Radiation protector: Chemicals that protect normal tissue from radiation injury have been sought by radiation oncologist. This compound should have a property of selectively protecting the healthy cells and not the malignant cells. Amongst them, a compound designated WR-2712 was the most promising in this regard.

Optimizing the Distribution of Radiation Dose

During irradiation of a tumor, the neoplastic tissues should receive high dose while the healthy tissues should receive a selectively low dose. To achieve this, following measures are used:

- *Electron beams* are used to treat the deep situated tumors located in skin, cervical lymph nodes metastases.
- *Super-voltage photons* are used to treat the deep situated neoplasms due to their skin sparing effect.
- *Multiple field technique* is used to treat the tumors of deeper tissues. Combination of two or more beams permits more uniform irradiation of the tumor, as compared with a single beam technique.
- *Shrinking field technique*—the malignant cells that constitute the wide peripheral extension of a tumor can be irradiated by a lower dose of irradiation because these cells are oxygenated. The cells constituting the central core of the tumor are more hypoxic and therefore require more doses of irradiation. So, the margins of healthy tissues should be treated to encompass the occult peripheral regional extension along with the known tumor volume. After a certain dose, the tumor mass regresses and the field can shrink to encompass only the central core of the tumor where the dose of radiation is increased. Hence, the surrounding healthy tissues are protected from higher dose of radiation and thus are at reduced risk of complications.
- *Radiolabelled antibodies*—antibodies against a protein specific to the tumor are generated in animals and then labelled with a radionuclide. When these antibodies are injected into a patient, they lodge over the tumor and expose it to irradiation from radionuclides. By this,

extremely high dose of radiations to tumor are possible with virtually no exposure to healthy tissues. But finding of the protein that is specific only to the tumor is difficult.

Optimizing the Timing of Irradiation

Hypofractionation

In it, the same total dose is delivered with a reduced number of fraction, e.g. 6000 rads in 10 fractions of 600 rads each, instead of 30 fraction of 200 rads each. But, this increased dose per fraction will reduce the total dose tolerance, producing a significant increase in the injury to late reacting healthy tissues and the total dose has to be reduced, which compromises the tumor control. So, hypofractionation is not recommended unless low doses to the tumor are acceptable, usually for palliative purpose or unless the patient has such a limited life expectancy that the injury to late reacting tissue is not of concern.

Hyperfractionation

If the same total dose is delivered with an increased number of fractions, it is called as hyper-fractionation. The minimum intervals between fractions that allow reasonable recovery of healthy tissue are 5-6 hours.

Accelerated Fractionation

Most of the tumors have intermitotic intervals of few days like acutely reacting tissue. The dose which increases injury to acutely reacting tissue will increase the injury to malignant cells. When the dose more than 200 rads per day are used in a single fraction, the injury to the late reacting tissues will increase. So, the accelerated radiation must be delivered in multiple conventional fractions per day with 5-6 hours gap between successive irradiations. Thus, in the accelerated fractionation, neither the fraction size is reduced nor increased but, there is an increase in radiations per day, normally with intervals of 5-6 hours.

Combined Strategies

A large number of possible permutations and combinations of hypofractionation, hyperfractionation and accelerated fractionations to treat the head and neck cancers are under investigation.

Reducing the Tumor Burden

Surgery helps to reduce the tumor burden to a level that can be safely irradiated by irradiation. Chemotherapy also helps in reducing the tumor burden in cases where the tumors are not resectable but morbidity of resection is more.

Complications of Radiotherapy

Osteoradionecrosis

Changes in the jaw bone after irradiation results from damage to the bones as well as impaired vascularity. The ready access of a highly varied microbial flora to heavily irradiated tissue is an important factor in the production of osteoradionecrosis. Gross necrotic lesion always begins in the interdental papilla of mandibular molar that was in the center of the field of radiation. The necrosis then extends to cervical gingiva, attached gingiva and the cheek mucosa. Patient may experience a transient prospective or thermal sensitivity of the teeth or perhaps a continuous dull toothache. Spontaneous death of pulp in an erupted teeth has also been reported. Pain in the jaw may be continuous and severe. After varying period of time, radiographic changes may appear. All trauma should be avoided to minimize the possibility of osteoradionecrosis. Deep gingival curettage and extraction are common contraindications in these cases.

Osteoradionecrosis is more easily prevented than treated. Whenever possible, the jaws, teeth and oral mucosal tissue should be shielded before radiation therapy in the area, unhealthy teeth are removed before radiation therapy. As a general rule, teeth which are in direct line of radiation should be rendered healthy enough to require little or no treatment for 5 years after radiation. Surgical intervention is contraindicated, except for the careful removal of sequestra that develops. Antibiotic therapy may reduce secondary infection. Hyperbaric oxygen therapy is also useful in these cases.

Radiation Mucositis (Fig. 16-55)

It is the inflammation of the oral mucosal membrane following radiotherapy. The basal layer of oral mucous membrane contains differentiating intermitotic cells.

Fig. 16-55: Mucositis occur due to radiotherapy.

These cells are sensitive to radiation. It develops in second week of radiotherapy. There are areas of redness and inflammation.

Later on, the mucous membrane breaks down to form pseudomembrane. After some period, mucous membrane becomes atrophic and thin. It is managed with application of topical anesthetizing agents for relief of pain, most commonly used is dyclonine hydrochloride.

Surgery

The surgical treatment of oral cancer as a primary modality is ablative (excisional) in nature. All the clinically detectable tumors must be excised with adequate margins of adjacent normal tissue, to ensure that the residual elements of microscopic disease do not remain within the surgical field. Different types of surgeries may be performed as follows. Surgical treatment has two distinctive phases: the resection of the tumor and the reconstruction of the defect.

Enbloc Resection

In it, removal of the entire tumor along with adequate margins of surrounding normal tissue in continuity, as one intact specimen is carried out, without incision through the involved tissue. Localized tumors without apparent or suspected cervical lymphatic involvement are treated by this method. Skin incisions are necessary to gain sufficient access for larger lesion. Resection should proceed along anatomical planes, whenever possible.

The extent of resection is determined by the margins of carcinoma or potentially involved tissue and is not spared to facilitate reconstruction. The surgeon must clear the site of the tumor at the first attempt. The chance of resecting residual tumor in a second operation is likely to be poor, as the demarcation between normal and pathological tissue becomes obscured by scarring and distortion of the anatomy.

Radical Neck Resection

Localized lesions with a suspected or proven cervical lymphatic involvement require a wide resection of the primary tumor within dissection of the involved neck. It involves excision of the cervical lymphatic system and removal of the sternocleidomastoid and omohyoid muscles, internal and external jugular veins, accessory nerve, submandibular gland and the inferior lobe of the parotid gland.

Commando Operation

It includes en bloc resection of primary tumor with the involved adjacent osseous structures and total radical neck dissection.

Palliative Therapy

In the tumors which are non-resectable, debulking procedure or deliberate subtotal removal is done. It provides palliation of acute symptom as pain relief, control of infection or alleviation of airway obstruction. The benefit of palliative therapy is temporary but quality of life can be improved for the patient.

Advantages of Surgical Treatment

- *During surgery*—immediate microscopic examination of the surgical margins can be performed during surgery, by the frozen technique, to ensure the adequacy of the excision. If the tissue shows microscopic involvement, the surgical margins should be widened.
- *Prosthesis management*—surgical defects can be satisfactory treated either by primary or secondary reconstructive procedures or by prosthesis rehabilitation.
- *Newly discovered lesion can be treated*—during surgery, newly discovered primary residual or recurrent tumor can be excised.
- *Adjunct treatment*—surgical treatment can be used as an adjunctive treatment in combination with other principal treatments like chemotherapy or radiotherapy.
- *Reduction of size of tumor before radiotherapy*—bulky tumors which have a central core of necrotic and hypoxic cells can be surgically reduced before radiotherapy, which is most effective of other treatment modalities like debridement of osteoradionecrosis following radiotherapy.

Reconstruction

Surgical Reconstruction

Reconstruction following resection of oral carcinoma is designed both, to repair the cosmetic defect and to reestablish the functions of the lost tissue. Conservation of lower border of mandible should be attempted, whenever feasible.

Mandible bone can be replaced by a variety of natural and alloplastic materials. Blocks of bone from hip or rib have commonly been used. Metal implants have also been used but suffer from problems of rejection and instability at the site where they abut the bone.

Nowadays, free bone graft secured by microvascular anastomosis has been used. In graft, bone remains viable and the graft may include periosteum, muscle and skin.

Following hemimandibulectomy, some patients are happy to tolerate a deformity. In these cases, direct soft tissue closure is feasible. Scar contraction, which will result in mandibular deviation, can be minimized by initial intermaxillary fixation and then interdental traction with training elastic bands.

In the maxilla, a split thickness skin graft is used to cover the defect and later, obturator replaces the lost tissue. Soft tissue loss may be repaired by a variety of methods using tissue of local, regional or distant origin.

Maxillofacial Prosthodontics

While surgeons can provide coverage of the defect following resection of oral carcinoma, the return of function such as speech and mastication and optimal cosmetic repair often rely on the skills of the prosthodontist. Two phase of prosthodontic care may be needed; the initial for the provision of surgical splints and after sufficient healing, definitive prosthetic appliance can be constructed and fitted.

Chemotherapy

It is described in Chapter 43: Anticancer Drugs.

New Therapies of Management of Oral Cancer

Over the last some years, there are many new methods for the management of oral cancer are available. These are as follows:

Photodynamic Therapy (PDT)

The first description of PDT was given in 1904 by Von Tappener and Jadlbauer.

- *Principle*—it involves selective uptake and retention of preadministered photosensitizer in a tumor. This is followed by irradiation with LASER of particular wavelength. This will lead to necrosis of tumor due to formation of singlet oxygen.
- *Photosensitizing agent*—the most commonly used agent is porphyrins. Porphyrins are a product of hemoglobin. Porphyrins which are used are photofrin, 5-aminolevulinic acid and foscan.
- *Technique*—
 - *Injection of photosensitizing agent*—porphyrins should be injected at dose of 2 mg/kg in the bloodstream.
 - *Absorption by tumors cells*—this is absorbed by all the cells of the body, but it remain more in contact with the tumors cells as compared to normal cells.
 - *Laser application*—after 48 hours of injection of porphyrins, tumor is activated by Laser of wavelength of 628-635 with an interval of 4-6 hours.
 - *Absorption of light by photosensitizer*—Laser light is absorbed by porphyrins with production of oxygen.
 - *Destruction of tumors cells*—this oxygen destroys cancer cells and damages the blood vessels. This will further reduce the blood supply to the tumors causing cell.
- *Indication*—it is more commonly used in superficial premalignant and malignant lesion of the oral cavity. It

is also used as adjunct therapy for poorly resected tumors.

- *Advantage*—it is cost effective, avoids systemic treatment, and applicable where surgery is not possible.
- *Disadvantage*—as there is limited penetration, it can cause tissue necrosis only to depth of 0.5-1 cm. It cannot treat metastasis.

Intralesional Chemotherapy

In this, drug is injected directly in the tumor. Drug remains concentrated in the tumor cells rather than spreading to the surrounding normal tissue. This will reduce the toxicity and side effect of the drug.

Intra-arterial Chemotherapy

In this, drug is injected into the arteries which are supplied to the tumor. This therapy can help to inhibit the tumors growth with high remission rate. There is also low toxicity reported.

Intensity Modulated Radiation Therapy (IMRT)

It is also called as 'tomotherapy'. IMRT delivers planned, specified doses of radiation therapy directly to cancer cells at the targeted site. This will spare the surrounding healthy tissue.

- *Principle*—in this, software is used to deliver a precise radiation beam, to particular area of tumor. This will decrease harmful doses to healthy tissue.
- *Component*—it consists of image acquisition software, treatment planning software, treatment simulator, platinum medical linear accelerator, dynamic multileaf collimator.
- *Advantage*—advantage includes reduced xerostomia, reduced risk of myopathy, and improved rate of tumor control.

Immunotherapy

It is designed to repair, stimulate and enhance the body's immune response. Previous effort with interferon, interleukins as immunomodulator got limited benefits. Nowadays, newer therapies like immunologic gene therapy and radioimmunotherapy are currently under trials.

- *Immunologic gene therapy*—in this, we are increased immunogenic potential of tumor cells.
- *Radioimmunotherapy*—also called as 'targeted radiotherapy'. In this, radionucleotides are linked to antibodies in order to deliver toxins directly to the tumor target. Most commonly used radionucleotides are Yttrium-90 and Iodine-131. Radioimmunotherapy is effective for treatment of lymphoma.

Gene Therapy

It is defined as introduction of functional genetic material into target cells to replace or supplement defective gene.

- *Principle*—precise amount of genetic material is transferred into each target cells allowing the expression of the gene product without causing toxicity. It targets dominantly on activated oncogenes on the cancer cells.
- *Gene addition therapy*—the role of p53, a tumor suppressor gene in cell regulation cycle and apoptosis is well established. Hence p53 gene transfer is safe and well tolerated.
- *Antisense RNA therapy*—gene expression can be inhibited by RNA. The antisense RNA can prevent activity of several known oncogenes. Such therapy can be directed towards cancer cells inhibiting the expression of oncogenes.
- *Suicide gene therapy*—it involves the introduction of gene into cell that enables a prodrug to be activated into an active cytotoxic drug. Most commonly used are herpes simplex virus thymidine kinase which selectively targets activity dividing cells.

Cancer Vaccines

Cancer vaccines include identifying unique cancer cell antigen, placing the gene for tumor antigen into viral vector and attaching an adjuvant to tumor molecules in order to stimulate an immune response against tumor cell. It is of two types:

- *Therapeutic vaccine*—it is used to treat cancer. It prevents further growth of existing cells and prevents recurrence. It includes *antigen/adjuvant vaccines* (specific protein fragments or peptides are used to stimulate immune response against tumor cells), *whole cell tumor vaccine* (this is taken from patient's own tumor, i.e. autologous or from other patient, i.e. allogenic) and *viral vector and DNA vaccines* (these are nucleic acid sequence of tumor antigen to produce cancer antigen proteins).
- *Preventive/prophylactic vaccines*—these are designed to target cancer causing viruses, thus preventing viral infection. Viral protein on the outside coat of cancer causing viruses is commonly used as an antigen to stimulate the immune system for preventive vaccine.

Introduction

Ulceration of the oral mucous membrane is a common occurrence in patients and may challenge the diagnostic acumen of the clinician. When observed in mouth, all these lesions have a similar appearance. As texture of oral mucosa is thin, mucosa is easily traumatized and infected by foods and oral mucosa in their appearance is nonspecific in the oral cavity. The ulcer is a Greek word meaning 'wound' or 'sore'. It has focus of necrotic tissue on the surface and a destroyed overlying epithelium.

An ulcer consists of margins, edges, floor and base. A *margin* is the junction between normal epithelium and the ulcer; so it is the boundary of the ulcer. An *edge* is the junction between a margins and the floor of the ulcer. Activity is maximum at the margins and edges of the ulcer.

Five common types of ulcer edges are seen.

- *Undermined edge*—it is mostly seen in tuberculosis ulcer. The disease causing the ulcer spreads and destroys the subcutaneous tissue faster than it destroys the skin. The overhanging skin is friable reddish blue and unhealthy.
- *Punched out edge*—it is mostly seen in gummatous ulcer or in deep tropic ulcer. The edges drop down at right angle to the skin surface.
- *Sloping edge*—sloping edge is seen mostly in healing, traumatic or venous ulcer which is reddish purple in color and consists of new healthy epithelium.
- *Raised and pearly white, beaded edge*—it is a feature of rodent ulcer. This type of edge develops in invasive cellular disease and becomes necrotic in the center.
- *Rolled out (everted) edge*—it is a characteristic feature of malignant ulcer. This ulcer is caused by fast growing cellular disease, the growing portion at the edge of the ulcer heaps up and spills over the normal skin to produce an everted edge.

- *Floor* is the exposed surface of the ulcer. The floor is composed of connective tissue fibrin with polymorpho-nuclear leukocyte infiltration. One must understand the difference between the floor (exposed surface within the ulcer) and the base (on which the ulcer rest) which is better felt than seen.

Formation of Ulcer

There are many ways by which ulcer develops. The simplest and most frequent development is through the destruction due to trauma. But many ulcers develop by systemic illness and hence, their pathogenesis is different. These lesions are preceded by the accumulation of fluid in subepithelial regions with the consequent formation of small blisters (vesicles) or large blisters (bullae) (**Fig. 17-1**). The presence of fluid, thickness of the epithelium and proliferation of the blister predispose to rupture; thus resulting in ulcer formation, e.g. bullous form of erythema multiforme.

Oral ulcerations are preceded by intense accumulation of inflammatory cells in the subepithelial regions, clinically visible as macular or papular eruptions. They may break down with resultant ulcer formation, as in certain cases of recurrent ulcerative stomatitis. Rarely, ulcerative lesions are preceded by an accumulation of fluid entirely within the confines of the epithelium forming an intraepithelial vesicle or bulla, as observed in pemphigus.

The life cycle of an ulcer consists of three phases (**Fig. 17-2**):

- *Extension*—the floor is covered with exudate and sloughs while the base is indurated. The edge is sharply defined and discharge is purulent or even blood stained.
- *Transition*—it is occupied for preparation for healing. The floor becomes cleaner, the slough separates; indurations of base diminish and the discharge becomes more serous. Small reddish areas of granulation tissue appear at the floor and these unite until the whole surface is covered.

Fig. 17-1: Formation of ulcer (diagrammatic representation).

- **Repair**—it consists of the transformation of granulation tissue to fibrous which gradually contracts to form scar. The edge of an ulcer becomes more shelving as the epithelium gradually extends to cover the floor. This healing edge consists of three zones.
 - **Outer**—it consists of epithelium, which appears white.
 - **Middle**—it is bluish, where the granulation tissue is covered by few layers of epithelium.
 - **Inner**—inner reddish zone of granulation tissue covered by a single layer of epithelial cells.

Classification of Ulcers

1st Classification According to Etiology and Pathology

Traumatic

- Due to mechanical irritation
- Chemical irritant
- Thermal burns
- Radiation burns
- Anesthetics necrosis
- Oral trauma from sexual practice

Infection

Viral infection

- Herpes simplex infection

Fig. 17-2: Life cycle of ulcer (diagrammatic representation)

- Herpes zoster
- Hand-foot and mouth disease
- Herpangina
- Chickenpox
- Smallpox
- Measles
- Infectious mononucleosis
- AIDS—HIV

Bacterial infection

- ANUG
- Tuberculosis
- Syphilis
- Gonorrhea
- Scarlet fever
- Diphtheria

Fungal infection

- Histoplasmosis
- Blastomycosis
- Mucormycosis
- Cryptococcosis

Allergy

- Local (stomatitis venenata)
- Systemic
- Secondary vaccinia
- Acrodynia

Neoplastic

- Squamous cell carcinoma
- Malignant melanoma
- Non-Hodgkin's lymphoma

Systemic disorders

Blood disorder

- Agranulocytosis
- Cyclic neutropenia
- Leukemia
- Aplastic anemia

Nutritional deficiency

- Scurvy

- Riboflavin deficiency
- Pellagra
- Protein deficiency
- Malabsorption syndrome
- Xerostomia
- Hand-Schüller-Christian disease
- Letterer Siwe disease
- Acrodermatitis enteropathica (Zinc deficiency)

Disease of unknown etiology

- Aphthous stomatitis
- Erythema multiforme
- Pemphigus
- Bullous pemphigoid
- Mucous membrane pemphigoid
- Erosive lichen planus
- Epidermolysis bullosa
- Systemic lupus erythematosus
- Dermatitis sialometaplasia
- Wegener's granulomatosis
- Eosinophilic ulcer of the oral mucosa

Syndromes

- Stevens-Johnson syndrome
- Behcet's syndrome
- Reiter's syndrome

2nd Classification (Burkitt's)

Acute multiple ulcers

- Acute herpetic stomatitis
- Erythema multiforme
- Herpes zoster infection
- Cytomegalovirus infection
- Coxsackievirus infection
- ANUG
- Allergic reaction

Chronic ulcers

- Pemphigus
- Pemphigoid
- Cicatricial pemphigoid
- Epidermolysis bullosa
- Para-neoplastic pemphigus
- Linear IgA disease
- Subepithelial bullous dermatoses
- Chronic bullous disease of childhood

Recurrent ulcers

- Recurrent aphthous stomatitis
- Behcet's disease

Single ulcer

- Traumatic ulcer
- Eosinophilic ulcer of tongue
- Histoplasmosis

- Blastomycosis
- Mucormycosis

Ulcers Associated with Trauma

Traumatic Ulcer

It is a frequently encountered ulcerative lesion of mouth. The common term used to denote a traumatic ulcer is 'decubitus ulcer', 'tropic ulcer', 'neutrons-tropic' and 'Bednar's ulcer'.

Etiology

- *Mechanical or physical*—it includes biting, sharp or malposed teeth or roots, sharp food, stiff toothbrush bristles, sharp margins of crown, fillings, denture, orthodontic appliances and faulty instrumentation.
- *Self-inflicted*—this is also one of the important cause of traumatic ulceration.
- *Chemical*—it results from caustic substances such as silver nitrate, phenol, TCA, formocresol, eugenol, eucalyptus oil, phosphorus and acetylsalicylic acid.
- *Thermal*—excessive heat in the form of hot fluid or food, on rare occasion the application of the dry ice, reverse smoking and hot instrumentation.
- *Electrical current*—application to the oral tissues may result in destruction and consequent ulceration, e.g. galvanism.
- *Others*—radiation burns, self-inflicted and iatrogenic.

Clinical Features

- *Age and sex*—it occurs in persons of any age, with equal frequency in both the sexes.
- *Site*—it may involve any region of the mouth but common on tongue, in mucobuccal fold, gingiva and palate.
- *Factors affecting appearance of ulcer*—the appearance of the traumatic ulcer varies markedly depending on the site of the injury, the nature and severity of trauma and the degree of secondary infection present.
- *Uncomplicated ulcer*
 - *Symptoms*—there is tenderness and pain in the area of lesion and it will be helpful to identify the cause of lesion. It may persist for few days and may last for weeks.
 - *Size and shape*—the most common variety of traumatic ulcer is single uncomplicated ulcer. It is of moderate size (from several millimeters to a centimeter or more in diameter). Shape of ulcer is usually round, oval or elliptical in shape and flat or slightly depressed (Fig. 17-3).
 - *Surface*—its surface consists of a serosanguineous or grayish serofibrinous exudate. It may be composed of a grayish necrotic slough which when removed,

reveals a red raw tissue base. In case of ulcer on vermillion border lip, it may have crusted surface due to absence of saliva.

- *Margins*—margin of the lesion is surrounded by a narrow border of redness.
- *Crater-like ulcer*—a traumatic ulcer may be crater like generally due to the result of repetitive trauma over a prolonged period thereby preventing healing.

Fig. 17-3: Traumatic ulcer seen intraorally on lingual side which is oval in shape.

- *Complicated ulcer*—in still other instances, the traumatic lesions are large and irregular (**Fig. 17-4**). These are the result of unusually severe traumatic episodes, such as a blow or a fall and are often accompanied by considerable edema, inflammation and swelling of the neighboring tissues.
- *Infected ulcer*—the infected ulcer is larger, more irregular and more protruding than the noninfected one and often it is covered with a thick layer of necrotic slough through which purulent exudate may be observed. In case of infected ulcer, painful regional lymphadenopathy is also present.

Fig. 17-4: Large and irregular ulcer occur due to blunt trauma to the patient.

- *Progress*—usually the simple and uncomplicated traumatic ulcer heals uneventfully in 5 to 10 days after onset and even without treatment. However, in the presence of secondary infection or repetitive trauma, longer healing period is required.

Diagnosis

- *Clinical diagnosis*—there is adjacent source of irritation present. History of the patient is also aid in coming to diagnosis.

Differential Diagnosis

- *Primary syphilitic lesion*—painless indurated edema, painless lymph nodes swelling.
- *Tubercular ulcer*—undermined flabby borders usually painless.
- *Dystrophic ulcer*—rarely, ulceration is caused by deficient blood supply (pressure vasoconstriction) due to local anesthesia. Main localization is the hard palate. Explanation is obtained from patient's history.
- *Necrotizing sialometaplasia*—it is rare, and limited to palate area. In this case, there are nonpainful areas of necrosis.

Management

- *Removal of causative agent*—causative agent should eliminate.
- *Persistent ulcer*—triamcinolone acetonide in emollient base before bedtime and after meals. A persistent ulcer, not responding to the foregoing regimen, should be surgically excised and the entire tissue must be sent for histopathological examination to rule out dysplastic changes.
- *Pain relief*—dyclonine HCL or hydroxypropyl cellulose films can be applied for temporary pain relief.
- *Chlorhexidine gluconate* (0.2%) ointment, chlorhexidine mouthwash or even topical local anesthetic to relive acute symptoms of pain.

Anesthetic Necrosis

In some cases, after administration of local anesthetics ulceration and necrosis can occur at the site of injection.

Causes

- *Faulty technique*—in some cases, due to subperiosteal injection, necrosis can occur.
- *Administration of excess solution*—anesthetic necrosis can also occur in case of excess administration of solution in the area of tissue firmly bound to bone.

Clinical Features

- *Location*—it is most commonly seen in hard palate area.
- *Appearance*—well-circumscribed lesion develops at the site of injection.
- *Sequestration of bone*—in some cases, sequestration of bone may occur.
- *Healing*—healing is usually delayed in this case.

Diagnosis

- *Clinical diagnosis*—ulceration and necrosis at the site of injection will easily diagnose this condition.

Management

- It is usually not required and lesion will heal on its own.

Oral Trauma from Sexual Practice

Orogenital sexual practice can lead to ulceration in the oral cavity.

Etiology

- *Fellatio*—in this, there is extravasation of erythrocyte which results from soft palate elevation and tensing against environment of negative pressure.
- *Cunnilingus*—as tongue is moved forwards taut frenum rubs against the incisal surface of mandibular incisor.

Clinical Features

- *Location*—it is more commonly seen on soft palate (fellatio) and floor of mouth (cunnilingus).
- *Fellatio lesion*—in this, there is submucosal palatal hemorrhage. Lesion appears as erythema, petechiae, purpura or ecchymosis.
- *Cunnilingus*—horizontal ulceration with linear fibrous hyperplasia can be seen.

Diagnosis

- *Clinical diagnosis*—history of patient will give clue to the diagnosis.

Management

- No treatment is required in this condition and lesion is resolved after some days.

Ulcers Associated with Infection

It is described in respective chapters.

Ulcers Associated with Allergic Reaction

Antigen-antibody reaction can cause clinical diseases of mouth and face.

Drug Allergy

It is also called as 'drug idiosyncrasy', 'drug sensitivity' and 'stomatitis or dermatitis medicamentosa'. Some patients have greater susceptibility to drugs and manifest reactions more readily than others.

Drugs which can most commonly cause drug reactions are aminopyrine, barbiturates, gold, bromide, penicillin, streptomycin, opioid and morphine derivative, amphetamine, etc. Drug allergy many time is caused by drug abuse/misuse of the drugs. Many times, patient goes for self-medication causing various types of drug sensitivity reaction in the body. While diagnosing, drug abuse history of patient should be carefully noted. In the history, patient may give vague complaint or he may be polydrug user.

Clinical Features

- *Symptoms*—patient complains of fever, and arthralgia.
- *Signs*—it is characterized by inflammation, ulceration and vesicle formation. Lymph nodes enlargement is the common occurrence.
- *Skin lesion*—the skin lesion is often of erythematous type (**Fig. 17-5**), as in erythema multiforme. They may be urticarial in nature.

Fig. 17-5: Erythematous fixed drug reaction seen on the hand of patient (Courtesy Dr Sanjay Pincha).

- *Fixed drug reaction*—fixed drug reactions may occur in those who are administered on repeated occasions, a drug to which they are sensitive. It consists of appearance of same reaction at the same site at every time (**Fig. 17-6**).

Fig. 17-6: Fixed drug reaction

Oral Manifestations

- **Symptoms**—xerostomia is most common complaint in drug abuser. This may occur due to pharmacological action on the salivary gland resulting in the hypofunction of the gland. Another complaint includes taste alteration, eating difficulties.
- **Signs**—in the early stages of reaction, vesicle or even bullae may be found on the mucosa (Fig. 17-7). Occasionally purpuric spots appear and angioneurotic edema is seen.

Fig. 17-7: Vesicles seen on the buccal mucosa in the patient of drug reaction (Courtesy Dr Revent Chole).

- **Appearance**—the oral lesions are diffused in distribution and vary in appearance from multiple areas of erythema (Fig. 17-8) to extensive areas of erosion or ulceration (Fig. 17-9).
- **Gingiva**—ulceration and necrosis of gingiva often resemble ANUG.
- **Periodontal problems**—severe periodontal problems can be present with sloughing of epithelium.

Fig. 17-8: Extensive area of erythema seen on the palate due to drug allergy (Courtesy Dr Revent Chole).

Fig. 17-9: Extensive erosion of lip seen in the drug allergy (Courtesy Dr Amit Parate).

- **Teeth**—severe erosion of enamel of teeth may occur due to snorting (through) of drug. Snorting will result in bathing of teeth with corrosive substance as drugs can go back to the oropharynx through posterior nasopharynx.

Diagnosis

- **Clinical diagnosis**—medical history of the patient should be properly taken. Mucosal ulceration may be clearly diagnosed after caseation of drugs.
- **Laboratory diagnosis**—serum evaluation of generic antinuclear antibodies should be carried out.

Differential Diagnosis

- **Recurrent herpes simplex infection**—it has got virus based etiology, prodromal symptoms. Lesion occurs usually in cluster.

- *Chronic pemphigus*—age, systemic symptoms, skin findings, immunofluorescence.
- *ANUG*—systemic symptoms, punched out ulcerations.
- *Mucous membrane pemphigoid*—eye involvement and chronic in nature.
- *Erythema multiforme*—lip changes, fever and malaise. In severe conditions, target or iris type of skin lesions are seen.

Management

- *Discontinuation of drug*—the signs and symptoms of drug allergy regress with discontinuing of the causative drug.
- *Antihistaminic drugs*—the acute signs may be relieved by administration of anti-histaminic drugs.
- *Topical corticosteroid*—localized reaction can be resolved by using topical corticosteroid.
- *Management of anaphylactic stomatitis*—this is managed by administration of adrenaline to patient.

Contact Allergy

It is caused by delayed type of hypersensitivity reaction to topical antigen. On the skin, it is referred as '*dermatitis venenata*' and oral lesions are referred as '*stomatitis venenata*'. The oral mucosa is less sensitive as compared to skin as saliva dilutes and removes many antigens. Another reason is that period of contact with the oral mucosa is brief as allergen is rapidly dispersed from the oral cavity. Oral lesions are rare due to number of '*Langerhans cells*', saliva which dilutes the allergens and washes them from the surface of the mucosa and digest with enzymes and a thin layer of keratin present on the oral mucosa.

Etiology

- *Medication*—it is caused by poison ivy, leather, rubber, nickel, medication or other chemicals.
- *Dental amalgam*—contact allergy to dental amalgam is caused by mercury, which is released during condensation.
- *Dental and cosmetic preparation*—it includes dentifrices, mouthwashes, denture powder, lip stick, cough drop and chewing gums.
- *Dental material*—it includes vulcanite, acrylic, metal alloy base.
- *Dental therapeutic agents*—it includes alcohol, antibiotics, chloroform, iodide, phenol, procaine and volatile oils.
- *Cinnamon flavoring*—cinnamon oil is used as flavoring agents in ice cream, soft drinks, alcoholic beverage, gum, candy, mouthwashes, and breathes freshener.

Clinical Features

- *Age*—it has got more predilections of females as compared to males.

- *Skin lesions*—there are typically itching erythematous areas with superficial vesicle formation, directly at the site where allergen contacts skin. The skin may become thickened and dry.
- *Symptoms*—burning is very common complaint rather than itching of skin.
- *Signs*—after the rupture of vesicle, erosion may become extensive and if secondary infection occurs, the lesion may be serious.

Oral Manifestations

- *Acute contact stomatitis*—in this case, barely visible redness is present. Edema may be present. If vesicle present, it gets ruptured to form erosive lesion.
- *Chronic contact stomatitis*—in this, as allergen remains more in contact with the oral mucosa, we can see white hyperkeratotic lesion (**Fig. 17-10**).

Fig. 17-10: Stomatitis venenata showing white hyperkeratotic lesion on lip.

- *Plasma cell gingivitis*—another oral manifestation is plasma cell gingivitis, which is characterized by erythematous edematous attached gingiva accompanied by cheilitis and glossitis.
- *Toothpaste contact allergy*—this will cause widespread erythema with desquamation of superficial layer.
- *Cinnamon contact allergy*—allergy of cinnamon oil or formalin present in toothpaste appears clinically as swelling, cracking and fissuring of lips, perioral desquamation and edema, angular cheilitis, swelling of gingiva and oral ulcerations. In some cases, significant thickening occur and it may resembles hairy leukoplakia.
- *Dental amalgam contact allergy*—in this condition, most commonly affected area is posterior buccal mucosa and lateral border of tongue. It present as white or erythematous patch with or without peripheral striae. These lesions can be termed as lichenoid reaction to dental amalgam.

Diagnosis

- *Clinical diagnosis*—by taking proper history you can make out relationship between contact allergen and mucosal lesion.
- *Patch test*—suspected allergen is placed on normal non-hairy skin, i.e. on upper portion of back. It remains in contact with skin for 48 hours. Then the patch is removed and after 2 to 4 hours, the area is examined for persistent erythema.

Differential Diagnosis

- *Herpetic gingivostomatitis*—exanthemas on hand, feet and mouth.
- *Erythema multiforme*—lip changes, target or iris type of skin lesions and malaise, in severe conditions.
- *Acute necrotizing ulcerative gingivitis*—starting on tips of papillae, mild fever and lymphadenopathy. Punched out ulcerations covered with gray-yellow to gray-green pseudomembrane.

Management

- *Removal of allergen*—removal of suspected allergen is the treatment of choice in case contact stomatitis.
- *Antihistamine therapy*—in severe cases, antihistamine therapy combine with topical anesthetic give good response.
- *Topical steroid*—this is indicated in chronic cases. Most commonly used are fluocinonide gel and dexamethasone elixir.

Secondary Vaccinia

It is also called as '*vaccinia autonoculata*'. Undesired skin or mucosal lesion, after smallpox vaccination, is caused by transfer of the contents of vaccination pustule to other parts of the body (**Fig. 17-11**). It is followed by formation of secondary lesions usually with weaker reaction than the one seen in case of primary inoculation.

Fig. 17-11: Secondary vaccinia showing erythematous lesion around the lip which appears after vaccination.

Secondary vaccinia may develop at the site of scratching possibly in already existing epithelial defect. Eyes, ears and areas of lips and tongue are possible sites. In this area, a patch develops that becomes vesicular than pustular.

After the development of crust, lesion is repaired with scar formation. Other ulcerative lesions such as primary lesion of syphilis, tuberculosis, aphthae of the major type should be differentiated. The history is important as secondary vaccinia appear about 5 to 7 days after inoculation.

Acrodynia

It is described in Chapter 20: Oral Pigmentation.

Angioedema

It is also called as '*angioneurotic edema*', '*Quincke's edema*', and '*giant urticaria*'. It is common form of edema which involves subcutaneous and submucosal connective tissue.

Etiopathogenesis

- *Food allergy*—angioedema most commonly due to food allergy.
- *Physical stimuli*—some physical stimuli like heat, cold, exercise, emotional stress, and solar exposure can cause mast cell degranulation which in turn release histamine with resultant angioedema.
- *Angiotensin converting enzyme inhibitors*—these are most commonly used for hypertension. It includes captopril, enalapril and lisinopril. These drug cause angioedema due to increase level of bradykinin.
- *Hereditary*—in some cases, angioedema results from activation of complement pathway.
- *Mechanism*—the mechanism of development of swelling is due to vasodilation brought about by the release of histamine like substances with subsequent transudation of plasma.

Clinical Features

- *Age and sex*—it affects both sexes equally, but it is infrequent in children while some cases originate at puberty.
- *Sites*—most often, the face and lips are involved, but sometimes the tongue also becomes swollen.
- *Symptoms*—a feeling of tenderness or an itching or prickly sensation sometimes precedes the urticarial swelling.
- *Appearance*—it typically manifests as a smooth, diffuse edematous swelling, particularly involving the face, around the lips (**Fig. 17-12**), chin and eyes, the tongue and sometimes, the hands and feet.

- *Signs*—edema may develop gradually in a matter of hours, but can also progress in minutes.
- *Parotid gland*—parotid gland may be affected in some cases.
- *Eyes*—the eyes may be swollen, shut and lips may be extremely puffy.
- *Progress*—the condition usually last for 24 to 36 hours, although some cases persist for several days.
- *Hereditary form*—the hereditary forms are more dangerous because there is visceral involvement. Vomiting and abdominal pain may occur and especially, dangerous edema of glottis can result in death through suffocation.

Fig. 17-12: Diffuse edema seen around the lip of the patient in case of angioedema

Diagnosis

- *Clinical diagnosis*—clinical presentation is typical with known antigenic stimulant.

Management

- *Removal of cause*—when etiological agent such as food can be discovered, its elimination from diet will prevent recurrent attacks. If it is associated with ACE inhibitor, the drug should be avoided in future.
- *Antihistamine drugs*—antihistaminic drugs (50 mg to 75 mg diphenylhydramine hydrochloride) can give prompt relief. In case of severe attack, intramuscular epinephrine should be administered.

Ulcers Associated with Malignancy

It is described in Chapter 16: Malignant Tumor of Jaw.

Systemic Disorders

It is described in other respective chapters.

Diseases of Unknown (Uncertain) Etiology

Aphthous Stomatitis

It is a common disease characterized by development of painful, recurrent, solitary or multiple ulcerations of the oral mucosa, with no other signs of any other disease.

Etiology

- *Immunological abnormalities*—mucosal destruction occur due to T cell mediated immunological reaction. IgG and IgM binding of the epithelial cells of the spinous layer of oral mucosa is seen in patients suffering from recurrent aphthous ulcer.
- *Genetic predisposition*—increased susceptibility to RAS is seen among the children of RAS positive parents. Specific HLA antigen has been identified in RAS patients. There is familial tendency for the occurrence of the disease. It is associated with HLA histocompatibility agents.
- *Microbial organism*—a pleomorphic transitional L-form of α -hemolytic streptococcus and streptococcus sanguis has been implicated as the causative agent of the disease. The reason for their occurrence is increased in antigenic exposure of the patient. Other microbial agents which are responsible are varicella zoster virus, adenovirus and cytomegalovirus.
- *Systemic factors*—small percentage of patients with recurrent aphthae have certain nutritional deficiency. Presence of a deficiency allows the expression of an unrelated, underlying tendency to ulceration. Other systemic factors like celiac disease, cyclic neutropenia, inflammatory bowel disease, MAGIC syndrome (mouth and genital ulcer with inflamed cartilage) and Sweet syndrome can also cause aphthous ulcer in oral cavity.

Precipitating Factors

- *Trauma*—local trauma including self-inflicted bites, oral surgical procedures, toothbrushing, needle injections and dental trauma can cause aphthous ulceration. The reason behind is that it decreases the mucosal barrier locally.
- *Endocrine conditions*—there is some relation between occurrence of aphthous ulcer and pregnancy, menstruation and menopause. There is remission of ulcers during pregnancy. Incidences of aphthae are greatest during menstruation. Ulcerations are maximum during postovulation period.
- *Stress*—acute psychological problems appear many times, to precipitate the attacks of the disease. Stress and anxiety can also precipitate the attack. You can see more

aphthous ulceration during exam period and less ulceration in vacation.

- *Cessation of smoking*—it increases the frequency and severity of RAS.
- *Allergic factor*—patients may have a history of asthma, hay fever and food or drug allergy.

Classification

- *Minor aphthae*—it is also called as 'canker sores' in which the ulcers are less than 1 cm in diameter and heal without scar.
- *Major aphthae*—it is called as 'Sutton's disease' or 'peradenitis mucosa necrotica recurrens' and the ulcers are over 1 cm in diameter and heal with scarring.
- *Herpetiform ulcers*—recurrent crops of dozens of small ulcers throughout the oral mucosa.
- *Aphthous ulcer with Behcet's syndrome*—recurrent ulcers associated with Behcet's syndrome.

Clinical Features

- *Age and sex distribution*—it usually occurs between second and third decades of life. It is common in women than men.
- *Sites*—it occurs most commonly on buccal and labial mucosa (**Fig. 17-13**), buccal and lingual sulci, tongue, soft palate, pharynx and gingiva.

Fig. 17-13: Minor aphthous ulcer seen on labial mucosa in female patient.

- *Prodromal symptoms*—it begins with prodromal burning, itching or stinging for 24 to 48 hours, before the ulcer appears. Ulcer gradually enlarges over next 48 to 72 hours.
- *Symptoms*—the lesion is typically very painful so, it commonly interferes with eating for several days.
- *Signs*—it begins as a single or multiple superficial erosion covered by gray membrane. It is surrounded by localized areas of erythema (**Fig. 17-14**) and develops within hours.

- *Shape*—lesions are round, symmetric and shallow but no tissue tags are present from the ruptured vesicles.
- *Course of disease*—multiple lesions are present but the number and size are frequently varied. Most patients have between 2 to 6 lesions at each episode and experience several episodes a year. The ulcers themselves generally persist for 7 to 14 days.

Fig. 17-14: Aphthous ulcer surrounded by zone of erythema and covered by gray membrane.

- *Minor aphthae (Figs 17-15A and B)*—size is 0.3 to 1 cm. These ulcers heal without scarring, within 10 to 14 days.
- *Major aphthae (Sutton's disease)*—size of lesion is larger than 1 cm (**Fig. 17-16**) and may reach upto 5 cm in diameter (**Fig. 17-17**). They interfere with speech and eating. Large portions may be covered with deep painful ulcers. The lesions heal slowly and leave scars, which result in decreased mobility of uvula and tongue (**Fig. 17-18**) and destruction of portions of oral mucosa.
- *Herpetiform ulcers*—multiple small shallow ulcers often up to 100 in number. It is found on any intraoral mucosal surface. It begins as small pinhead size erosions that gradually enlarge and coalesce. Lesions are more painful than would be suspected by their size. It is present continuously for one to three years, with relatively short remission. Patient gets relief immediately with 2% tetracycline mouthwash.

Diagnosis

- *Clinical diagnosis*—diagnosis is made from clinical presentation and exclusion of other disease.

Differential Diagnosis

- *BMMP and pemphigus*—absence of vesicles and blebs.
- *Bednar's aphthae*—these are not aphthae as such but traumatic lesions on the palatal mucosa of a newborn which develop through careless wiping of the oral cavity.

Figs 17-15A and B: Minor aphthous ulceration seen on labial mucosa and gingiva. Size of ulcer is around 0.5 mm.

Fig. 17-16: Major aphthous ulcer seen on maxillary tuberosity area with size about 2 cm.

- *Cyclic neutropenia*—appearance with marked period of 3 weeks of compromised general condition, blood picture and granulocyte count should be taken into consideration.

Fig. 17-17: Sutton's disease measuring about 5 cm in diameter occurring on the soft palate (Courtesy Dr Soni).

Fig. 17-18: Major aphthous ulcer seen on the lateral border of tongue (Courtesy Dr Chole).

- *Erythema multiforme*—aphthous ulcers are uniform in distribution, crusted appearance with scaly crust of lips, target lesions and erosion of different sizes.
- *Necrotizing sialometaplasia*—rarely, limited to hard and soft palate, usually painless.
- *Lupus erythematosus and psoriasis*—white components are present.
- *Erosive lichen planus*—whitish changes in border lesion.
- *Primary syphilitic lesion*—painless, indurated edema, painless swollen lymph nodes.
- *Atrophic candidiasis*—smear test should be done for candida organism.
- *Herpetic stomatitis*—patient has fever, malaise and nausea with pinpoint size ulcers of gingiva.
- *Herpangina*—affects children in late summer and early winter and localized on soft palate.

- *Hand, foot and mouth disease*—vesiculo-ulcerative lesions occur simultaneously in the oral cavity and on hands and feet.
- *Recurrent herpes simplex infection*—difference between herpes simplex and aphthous ulcer are described in **Table 17-1**
- *Bite wound after local anesthesia*—it is described in **Table 17-2**.
- *Aphthae in Behcet's syndrome*—it is described in **Table 17-3**.
- *Squamous cell carcinoma*—it is described in **Table 17-4**.

Table 17-1: Difference between herpes simplex and aphthous ulcer

Features	Recurrent aphthous ulcer	Recurrent intraoral herpes infection
Age	Wide range	At any age, but more common in middle and older age.
Location	On freely movable mucosa like lip, buccal mucosa, tongue, mucobuccal fold and soft palate.	On buccal mucosa tightly bound to periosteum, hard palate, gingiva and alveolar ridge.
Initial lesion	Erythematous macule or papule which undergoes central blanching followed by necrosis and ulceration.	Clusters of small discrete gray or white vesicles without red erythematous halo, vesicle quickly ruptures forming small punctured ulcer of 1mm or less in diameter.
Mature lesion	Shallow ulcer, 0.5 to 2 cm in diameter, yellow necrotic center, regular border contrast, erythematous halo.	Shallow ulcer, larger than 0.5 cm lesions coalesce to form large lesions.
Number of lesion	Occur single	Usually several small punctate ulcers in clusters, regular border, round, variable erythematous halo.
Histology	Nonspecific ulcer	Epithelial cell with ballooning degeneration, multi-nucleated giant cell, virus particles

Table 17-2: Bite wound after local anesthesia

Chronic recurrent aphthae	Bite wound after local anesthesia
Roundish oval form	Irregular ragged margins
Erythematous halo	Inflammatory erythema is ill defined
Very painful	Moderately painful
Recurring appearance at different location	Lesion occurs only once

Table 17-3: Aphthae in Behcet's syndrome

Chronic recurrent aphthae	Aphthae in Behcet's syndrome
Aphthae is the only symptom	Mouth aphthae are part of a systemic disease
Superficial ulceration	Deep ulceration
Aphthae mostly in the anterior region of mouth	Aphthae also in the posterior region of mouth

Table 17-4: Squamous cell carcinoma

Aphthae (major type)	Squamous cell carcinoma
At any age	More than 50 years of age
History of quick development	Slow development
Very painful at onset, later moderately painful	Little or no pain
Inflamed border edges	Thickened edges
Lymph node often painfully swollen	Lymph nodes swollen without pain
Associated edema	Surroundings are not irritated
Palpation noncontributing	Borders indurated

Management

Minor aphthous or herpetiform aphthous

- *Topical corticosteroid*—topical corticosteroid triamcinolone acetonide 3 to 4 times daily. Other topical steroids which can be used are betamethasone syrup and 0.01% dexamethasone elixir. It should be used by *rinse and expectorate method*. In patient with localized ulceration, 0.05% betamethasone dipropionate or 0.05% fluocinonide can be used.
- *Anesthetic cream*—topical protective emollient base (Orabase) should be given.
- *Tetracycline mouth wash*—topical tetracycline mouth wash (250 mg per ml) use four times daily for 5 to 7 days produces good response in nearly 70% of the patients.
- *Nutritional supplement*—replacement therapy with vitamin B₁₂, ferritin, folate and iron is also indicated.
- *Maintenance of oral hygiene*—chlorhexidine mouthwash is also given to patient to maintain oral hygiene.

Severe cases

- *Injection of steroid*—Injection of corticosteroid directly in lesion should be given. Most commonly used are triamcinolone acetonide.
- *Topical application*—topical preparation like 0.05% clobetasol cream, fluocinolone gel is also used. Triamcinolone tablet can be dissolved directly over the lesion.
- *Beclomethasone dipropionate spray*—this is recommended in severe case of aphthous ulcer where it is difficult to reach. It is usually given in case of aphthous ulcer of tonsillar pillar.

- **Systemic steroid**—in resistant cases, systemic steroid can be given. Most commonly prednisone or betamethasone syrup in a *swish and swallow method* (patient gargle the syrup and then swallow it) is given. In some cases prednisone tablet is also given.
- **Chlortetracycline**—it is used as mouth rinse to be flushed over the affected region, for at least 2 minutes provides relief from pain.
- **Surgery**—surgical removal of aphthous ulcer can also be used. Laser ablation shortens the duration and decreases associated symptoms.
- **Other medication**—many other medication have been tried to resolve the disease. The success of the therapy is highly variable. The other therapies which can be used are dapsone, thalidomide, amlexanox, topical 5-aminosalicylic acid, azelastine hydrochloride, colchicines, cyclosporine, gamma globulin, hydrogen peroxide, pentoxifylline, prostaglandin E-2 gel, sucralfate, interferon alpha and levamisole can be used.

Erythema Multiforme

It is acute inflammatory disease of the skin and mucous membrane that causes a variety of skin lesions, hence the term 'multiforme'.

Etiology

- **Immune mediated disease** that is indicated by the deposition of immune complexes in the superficial microvasculature of the skin and mucous membrane or cell mediated immunity.
- **Drugs** like sulfonamides, trimethoprim, nitrofurantoin, phenylbutazone, digitalis, birth control pills and penicillin.
- **Microorganisms**—microorganisms like mycoplasma pneumoniae and herpes simplex virus.
- **Other factors**—vaccination, radiation therapy and occasionally other disease like Crohn's disease, ulcerative colitis and infectious mononucleosis can also predispose to this condition.

Types

- **Erythema multiforme minor**—it is self-limiting form and is less severe form and lesion.
- **Erythema multiforme major**—it is severe form may be present as Steven Johnson syndrome.
- **Toxic epidermal necrolysis**—it is the most severe form of erythema multiforme. It occurs due to increased apoptosis of the epithelial cells.

Clinical Features

- **Age and sex**—it is most frequently seen in children and young adults and is rare after the age of 50. It affects males more than females.

- **Sites**—most common area, involved are hands, feet, extensor surfaces of elbow and knees.
- **Onset**—it has got acute or explosive onset with generalized symptoms such as fever and malaise. It may be asymptomatic and in less than 24 hours, extensive lesions of oral mucosa may appear (**Fig. 17-19**).

Fig. 17-19: Large lesion seen on tongue which is showing bleeding tendency.

- **Appearance**—it is characterized by macule or papule, 0.5 to 2 cm in diameter, appearing in segmental distribution. Typical skin lesions of erythema multiforme may be non-specific macule, papule and vesicle.
- **Bull's eye or target lesion**—target or iris or bull's eye lesion consists of central bulla or pale clearing area, surrounded by edema and band of erythema.
- **Prognosis**—morbidity is high due to secondary infection, fluid and electrolyte imbalance or involvement of lungs liver and kidneys.
- **Stevens-Johnson syndrome**—in Stevens-Johnson syndrome, there is generalized vesicles and bullae formation involving skin, mouth, eyes and genitals.
- **Toxic epidermal necrolysis**—it is also called as 'Lyell's disease'. It occurs secondary to drug reaction and results in sloughing of skin and mucosa in large sheets. It is more common in female. It appears as patient is badly scalded. It is managed in burn centers where necrotic skin is removed under general anesthesia and healing takes place under sheets of porcine xenografts.

Oral Manifestation

- **Prevalence**—it occurs along with skin lesions in 45% of the cases.
- **Sites**—lip is prominently involved followed by buccal mucosa, palate, tongue and face.
- **Appearance**—oral lesions start as bullae, on an erythematous base and break rapidly into irregular ulcers.

Fig. 17-20: Extensive lesion of buccal mucosa seen in erythema multiforme

Figs 17-21A and B: Hemorrhagic crusting of lip seen in erythema multiforme patient (Courtesy Dr Chole).

- **Symptoms**—patient cannot eat or swallow and blood tinged saliva drools.
- **Signs**—the lesions are larger, irregular, deeper, and often bleed very freely. In full blown cases, lips are extensively involved (**Fig. 17-20**) and large portions of the oral mucosa are denuded of epithelium. Sloughing of mucosa and diffuse redness with bright red raw surface is seen.
- **Lips lesion**—lip lesion are extensive with presence of hemorrhagic crusting (**Figs 17-21A and B**).
- **Healing**—healing occurs in 2 weeks.

Diagnosis

- **Clinical diagnosis**—hemorrhagic crusting of lip with target lesion seen on skin will diagnose erythema multiforme.
- **Laboratory diagnosis**—the cutaneous or mucosal lesions generally exhibit intracellular edema of the spinous layer of epithelium and edema of superficial connective tissue, which may produce subepidermal vesicle. There is zone of liquefaction degeneration in the upper layer of the epithelium with intraepithelial vesicle formation and thinning, with frequent absence of the basement membrane.

Differential Diagnosis

- **Viral lesions like primary herpetic gingivo-stomatitis**—they are small, round, symmetrical and shallow but erythema multiforme lesions are larger, irregular, deeper, often bleed. Gingival involvement is rare in erythema multiforme.
- **Pemphigus vulgaris**—less associated inflammation, progressive course, immunological auto-antibodies against intercellular substance.
- **Mucous membranes pemphigoid**—slow development- eye changes, chronic course and frequent participation of gingiva.
- **Allergic reactions**—target lesions are absent.
- **Erosive lichen planus**—onset less acute, whitish lichen design on the border of erosion and skin changes.
- **Xerostomia**—mucosa is dry.
- **Herpetic gingivostomatitis** (**Table 17-5**).
- **Systemic lupus erythematosus** (**Table 17-6**).
- **Pemphigus** (**Table 17-7**).

Table 17-5: Herpetic gingivostomatitis

Erythema multiforme	Herpetic gingivostomatitis
Younger adults usually affected	Small children usually affected
Exudative component in the foreground: typical hemorrhagic crusty scales	Aphthous lesions over general stomatitis
Skin changes (target lesion)	No skin changes

Table 17-6: Systemic lupus erythematosus

Erythema multiforme	Systemic lupus erythematosus
Acute onset	Systemic disease with chronic course
Self-limiting course	Often lethal course
Skin changes (target lesion)	Polymorphous skin changes
Intraoral changes, especially in the anterior part of the oral cavity	Changes in the whole oral cavity with distinct erythematous component

Table 17-7: Pemphigus

<i>Erythema multiforme</i>	<i>Pemphigus</i>
Primarily in young adult	Usually in older patients
Acute disease	Chronic disease
Erosive crusty changes	Pustulopapular vegetation
Skin changes (target lesion)	Skin changes in intertrigous area
Negative Nikolsky's sign	Positive Nikolsky's sign

Diagnosis

- *Clinical diagnosis*—bull's eye lesion with hemorrhagic crusting of lip is typical of erythema multiforme.
- *Laboratory diagnosis*—biopsy shows subepithelial or intraepithelial vesiculation.

Management

- *Topical steroid*—mild cases can be managed by topical application of steroid.
- *Removal of cause*—if you are able to identify causative drug, its use should be discontinued.
- *Rehydration*—if patient is dehydrated due to pain then intravenous rehydration should be carried out. Patient should be given soft liquid diet.
- *Topical anesthetic mouthwash*—this is given to manage the pain in the oral cavity.
- *Systemic steroid*—in severe cases, systemic 30 mg/day prednisone or methyl prednisone for several days should be given. Dose should be tapered after the symptoms subside (**Fig. 17-22**).
- *Acyclovir*—it is indicated in erythema multiforme associated with HSV.
- *Management of toxic epidermal necrolysis*—this patient is managed in burn center. Administration of pooled human immunoglobulin is also effective in TEN. The reason behind is that it induced blockade of Fas ligand which induce epithelial cell apoptosis.

Fig. 17-22: Erythema multiforme lesion after week of steroid therapy (Courtesy Dr Bhaskar Patle).

Pemphigus

It is autoimmune disease involving the skin and mucosa and characterized by intraepidermal bulla formation.

Types

- *Pemphigus vulgaris*
- *Pemphigus vegetans*
- *Pemphigus foliaceus*
- *Pemphigus erythematosus*

Pemphigus Vulgaris

Mechanism

- *Epithelial cell separation*—binding of IgG antibody to Pemphigus antigen leads to epithelial cell separation by triggering complement activity or plasminogen plasmin system. Separation of cell takes place in lower layer of stratum spinosum.
- *Associated factors*—pemphigus may be associated with thymoma, myasthenia gravis or with multiple autoimmune disorders. It may be triggered by drug therapy like penicillamine, penicillin, phenobarbitone and captopril.

Clinical Features

- *Age and sex*—it is seen in 5th to 6th decades of life and male to female ratio is 1:1, with whites more commonly affected.
- *Size*—thin walled bullae or vesicles varying in diameter from few mm to several centimeters arise on normal skin or mucosa (**Fig. 17-23**).

Fig. 17-23: Thin walled bullae seen on back of patient (Courtesy Dr Bhaskar Patle).

- *Signs*—these lesions contain a thin, watery fluid shortly after the development, but this may soon become purulent or sanguineous. They rapidly break and continue to extend peripherally, eventually leaving large areas of denuded skin (**Fig. 17-24**).
- *Nikolsky's sign*—after giving application of pressure to an intact bulla, the bulla will enlarge by extension to

Fig. 17-24: Peripheral extension of vesicular lesion seen in pemphigus (Courtesy Dr Tapasya Karamore).

apparently normal surfaces. Another characteristic sign of the disease is that pressure to an apparently normal area will result in formation of new lesion. This phenomenon is called as Nikolsky's sign. It results from upper layer of skin pulling away from the basal layer. It is caused by prevesicular edema which disrupts the dermal-epidermal junctions.

- **Course**—the course of pemphigus vulgaris is a variable one; the disease terminating in death or recovery within a few days or weeks or it may get prolonged over a period of months or even years.

Oral Manifestations

- **Prevalence**—in 90% of the cases, oral lesions develop and in 60% cases, they occur first.
- **Sites**—initial lesion most frequently occurs on buccal mucosa because the epithelium demonstrates less intercellular substance and fewer intercellular junctions making the area more susceptible to acantholysis. Palate and gingiva are other common sites of involvement.
- **Onset**—oral lesions begin as classic bullae on non-inflamed base with formation of shallow ulcers as bullae break rapidly (**Fig. 17-25**).
- **Symptoms**—lesions bleed easily and are tender on palpation. The pain may be so severe that the patient is unable to eat.
- **Signs**—thin layer of epithelium peels away in an irregular pattern leaving denuded base.

Fig. 17-25: Ulcerative lesions seen on tip of tongue in pemphigus (Courtesy Dr Tapasya Karamore).

- **Nikolsky's phenomenon**—the oral lesions may exhibit Nikolsky's phenomenon and may be denuded by peripheral enlargement of the lesion (**Fig. 17-26**).
- **Margins**—the lesion may have ragged borders and be covered with white or blood tinged exudate. Edges of the lesion may extend peripherally.
- **Gingiva**—diffuse erythematous involvement of gingiva.

Fig. 17-26: Extensive lesion of oral mucosa in case of pemphigus showing denuded epithelium (Courtesy Dr Chole).

Pemphigus Vegetans

Types

- **Neumann type**—it is more common and early lesions are similar to those seen in pemphigus vulgaris.
- **Hallopeau type**—in hallopeau type; pustules, not bullae, are the initial lesions which are followed by verrucous hyperkeratotic vegetations.

Clinical Features

- **Incidence**—it occurs in 1% to 9% of the cases.

- *Appearance*—the flaccid bullae become eroded and forms ‘vegetations’ on some of the erosions.
- *Signs*—these fungoid masses become covered by purulent exudate and exhibit inflamed borders, frequently occur first on nose and in the mouth or axillae. The disease usually terminates in pemphigus vulgaris.

Oral Manifestations

- *Granular or cobblestone appearance*—gingival lesions are lace like ulcers with purulent surface on red base or have granular or cobblestone appearance.

Other Variant of Pemphigus

- *Pemphigus foliaceus*—it is a relatively mild form of pemphigus, which is most common in older adults. It is manifested by characteristic early bullous lesions which rapidly rupture and dry to leave masses of flakes on scales suggestive of an exfoliative dermatitis or eczema.
- *Brazilian pemphigus*—it is a mild endemic form of pemphigus foliaceus found in tropical regions, particularly in Brazil. It is seen in children and frequently in family groups.
- *Pemphigus erythematosus*—it is also called as *Senear-Usher syndrome*. It is form of disease which is characterized by the occurrence of bullae and vesicles concomitant with the appearance of crusted patches resembling seborrheic dermatitis or even lupus erythematosus. Most cases ultimately terminate in pemphigus vulgaris or foliaceus. The skin manifestations in any form of pemphigus may be accompanied by fever and malaise.
- *Paraneoplastic pemphigus*—it is associated with neoplasm like lymphoma or chronic lymphocytic leukemia. It occurs due to cross reactivity between antibodies produce by tumor and antigen associated with desmosomal complex. These multiple vesiculobullous lesion affects skin and oral mucosa. There is also palmar and planter bullae present which is not features of other type of pemphigus. In some cases, cicatrizing (scarring) conjunctivitis may develop.

Diagnosis

- *Clinical diagnosis*—positive Nikolsky’s sign with vesicular and bullous lesion seen on trunk, leg and oral mucosa.
- *Laboratory diagnosis*—basic defects are intraepithelial and is demonstrated as acantholysis as in *stratum spinosum*.
- *Tzanck smear*—it is done to demonstrate Tzanck cells which often are found lying freely within the vesicular space.
- *Indirect immunofluorescent antibody test*—antibodies against intercellular substance can be seen. The titers of

antibody are directly related to the level of the clinical disease.

- *Direct test*—antibody will bind the immunoglobulin deposit in the intercellular substance and show positive fluorescence under fluorescence microscope.

Differential Diagnosis

- *Recurrent aphthous stomatitis*—severe but heals and recurs; but in Pemphigus lesion, course extends over a period of weeks or months. Lesions of Pemphigus are not round, symmetrical but are shallow and irregular and often have detached epithelium at the periphery.
- *Dermatitis herpetiformis*—mucosal involvement is rare, Tzanck test and Nikolsky’s sign are negative. Skin changes are polymorphic.
- *Viral infection*—bullae are larger.
- *Bullous pemphigoid*—usually not intraoral; immunofluorescence can be done.
- *Erythema multiforme*—polymorphous appearance, systemic symptoms, acute onset, older patients.
- *Bullous drug induced exanthema*—negative-Tzanck test and Nikolsky’s sign, the vegetating variant can be confused with syphilitic patches and with other vegetating lesions caused by bromides, iodides, with acanthosis nigricans (pigmentation) and angular cheilitis.
- *Pyostomatitis vegetans*—pustule formation.
- *Wegner’s granulomatosis*—involvement of the nasal cavity, histology.
- *Benign mucous membrane pemphigoid* (Table 17-8).

Table 17-8: Benign mucous membrane pemphigoid

Pemphigus	Mucous membrane pemphigoid
Blisters filled initially with clear, and later with yellowish cloudy fluid.	Blisters do not get cloudy, change into erosions.
Pressure over blister causes it to shift laterally into adjacent mucosa.	Lateral shifting of the blisters usually not possible.
Skin changes.	Skin involvement less frequent.
No eye symptoms.	Eye involvement in 80% of the cases.
Severe illness picture.	No influence on general condition.
Painful lesions.	Blisters without symptoms.

Management

- *Corticosteroids*—topical or systemic prednisone. Systemic prednisone is used to bring disease under control and once the disease is under control, dose of prednisone is reduced.
- *Combination therapy*—high dose of corticosteroids are combined with immuno-suppressive drugs such as cyclosporine or azathioprine.

- *Plasmapheresis*—it is useful in patients refractory to corticosteroids.
- *Others*—parenteral gold therapy, etretinate and dapsone can also be used.
- *Newer therapy*—administration of 8-methoxypsoralen, followed by exposure of peripheral blood to ultraviolet radiation.

Bullous Pemphigoid

It is also called as '*para-pemphigus*', or '*aging pemphigus*'. In this, the initial defect is subepithelial in the lamina lucida region of the basement membrane. It is associated with anti-basement membrane antibodies which are detected in the basement membrane.

Clinical Features

- *Age and sex distribution*—it occurs chiefly in adults over the age of 60 is self-limiting and rarely lasts over 5 years.
- *Onset*—pruritus is seen in patient which is followed by develop of multiple bullae. Bullae do not extend peripherally and remain localized; heal spontaneously.
- *Skin lesion*—skin lesions begin as generalized non-specific rash, commonly on the limbs, which appear as blisters on inflamed skin; itching precedes.
- *Progress*—it may persist for several weeks to several months before ultimate appearance of vesiculo-bullous lesions.
- *Signs*—these vesicle and bullae are relatively thick walled and may remain intact for several days (**Fig. 17-27**). Rupture does not occur although it leaves raw eroded areas which heal rapidly.

Fig. 17-27: Intact bulla seen on hand of patient in bullous pemphigoid.

Oral Manifestations

- *Sites*—vesicles and ultimately erosion may develop not only on the gingival tissue but any other area such as the buccal mucosa, palate (**Fig. 17-28**), floor of the mouth and tongue.

- *Symptoms*—oral lesions are smaller, form more slowly and are less painful.
- *Gingiva*—gingival lesions consist of generalized edema, inflammation, desquamation, and localized areas of discrete vesicle formation.

Fig. 17-28: Ruptured bulla seen on palate of the patient in bullous pemphigoid (Courtesy Dr Soni).

Diagnosis

- *Clinical diagnosis*—bullae present on skin which does not extend peripherally. Ruptured bulla can be seen.
- *Laboratory diagnosis*—the vesicle and bullae are subepidermal and non-specific. Epithelium appears normal. The vesicle contain fibrinous exudate admixed with occasional inflammatory cells.
- *Indirect immunofluorescence antibody test*—lesions will demonstrate circulating IgG antibodies against basement membrane antigen.
- *Tzanck smear* negative to acantholytic cells.
- *Direct immunofluorescence testing and complement fixation test*—positive specimen will demonstrate IgG and complement in the basement membrane zone.

Management

- *Systemic steroids*—moderate doses of prednisone can be given. Later on, prednisone should be given in alternate day therapy.
- *Immunosuppressive therapy*—immunosuppressive drug like azathioprine may be given in this patient.
- *Other therapy*—other therapy like dapsone, tetracycline, and niacinamide can be given in this patient.

Benign Mucous Membrane Pemphigoid

It is also called as '*cicatricial pemphigoid*'. It is a disease of unknown etiology but probably is autoimmune in nature. In this condition, tissue bounded autoantibodies are

directed against basement membrane. The word cicatricial is derived from the word *cicatrix* meaning scar.

Clinical Features

- *Age and sex*—it occurs more commonly in patients over 50 years of age and female to male ratio is 2:1.
- *Sites*—typically, the vesiculo-bullous lesions occur on the oral mucus membrane, conjunctivae and skin. The other mucous membranes involved are those of nose, larynx, pharynx, esophagus, vulva, vagina and penis.
- *Symptoms*—involvement of esophagus and trachea may cause strictures leading to difficulty in swallowing or breathing.
- *Eyes*—adhesions may develop between bulbar and palpebral conjunctivae resulting in obliteration of the palpebral fissure with opacity of the cornea, frequently leading to blindness. Scarring can lead eyelid to turn inward (*entropion*). This will cause eyelashes to rub against cornea and globe (*trichiasis*).
- *Healing*—it may lead to scarring of affected area.

Fig. 17-29: Erosion seen on buccal mucosa of patient in benign mucous membrane pemphigoid (Courtesy Dr Chole).

Oral Manifestations

- *Sites*—it occurs on gingiva, buccal mucosa and palate. The mouth may be the only site involved.
- *Onset*—the mucosal lesions are also vesiculo-bullous in nature, but appear to be relatively thick walled and for this reason may persist for 24 to 48 hours before rupturing and desquamation.
- *Appearance*—there may be formation of ulcer, which surrounded by zone of erythema. There may be erosion on cheek (Fig. 17-29) and vesicles on palate and narrower peripheral extensions.
- *Signs*—after rupture of vesicle surface epithelium is lost leaving raw red bleeding surface (Fig. 17-30).

- *Desquamative gingivitis*—gingiva is edematous and bright red, involvement is patchy and diffuse.
- *Healing*—the oral lesions rarely produce scars.

Fig. 17-30: Same patient showing ulceration on inner aspect of lip.

Diagnosis

- *Clinical diagnosis*—desquamative gingivitis with erosive lesion seen in oral cavity with typical eye lesion will diagnose these conditions.
- *Laboratory diagnosis*—the vesicle and bullae are sub-epidermal rather suprabasilar and there is no evidence of acantholysis. Low titers of serum antibody.
- *Direct immunofluorescent study*—it will show positive fluorescence for immunoglobulins and complement in basement membrane zone, i.e. in intercellular substance of prickle cell layer of epithelium.

Differential Diagnosis

- *Pemphigus vulgaris*—painful erosions, eye involvement only in more severe cases, rapid appearance of blister, rapid transformation into erosion, thinner walled larger erosions.
- *Bullous pemphigoid*—primary site is skin.
- *Erythema multiforme*—acute onset, feeling of malaise, target lesions polymorphous picture and often self-limiting.
- *Behcet's syndrome*—erosive lesions, no bullae, no desquamative gingivitis and genital lesions.
- *Herpetic gingivostomatitis* (Table 17-9).

Management

- *Topical steroid treatment*—disease can be controlled by topical application of steroid many times daily. In case of gingival lesion, flexible mouth guard may be fabricated to use as carrier for the corticosteroid medication.
- *Systemic steroid and immunosuppressive therapy*—if topical treatment is not successful, systemic corticosteroid with

Table 17-9: Herpetic gingivostomatitis

Mucous membrane pemphigoid	Herpetic gingivostomatitis
Development of bullous erosive lesion on apparently healthy mucosa	Prodromal –feeling of tension, burning, vesiculo-erosive merging lesion
Can appear on any region of the mucosa	Almost only on the hard palate and gingiva
Usually in older patients	Independent of age
Eye changes are frequent	No eye involvement
Epithelial rest is at border	No epithelial rest at borders
Chronic course with intermittent bouts	Long asymptomatic interval between recurrence

immunosuppressive agents like cyclophosphamide may be used.

- *Dapsone therapy*—this sulfa drug derivative can be used as an alternative therapy. It should not be used in glucose 6 phosphate dehydrogenase deficiency.
- *Tetracycline and nicotinamide therapy*—another alternative therapy of tetracycline or minocycline and niacinamide can be given. It should be given in divided doses of 0.5 to 2 gm each.
- *Ophthalmologist consultation*—patient should be send to ophthalmologist for eye lesion.

Familial Benign Chronic Pemphigus

It is also called as *Hailey-Hailey* disease. It is uncommon disease transmitted by autosomal dominant gene. Heat and sweating amplify the outbreak of the lesion while spontaneous remission may occur in cold weather.

Clinical Features

- *Age and sex*—it is usually manifested during adolescent or young life with no predilection for sex.
- *Sites*—the most common sites are flexure surfaces of the axillae and groin, the neck and the genital area.
- *Appearance*—the lesions develop as small groups of vesicles appearing on normal or erythematous skin, which soon rupture to leave eroded, crusted areas
- *Nikolsky's sign*—they enlarge peripherally but heal in center with Nikolsky's sign positive.
- *Symptoms*—tender and enlarged regional lymph nodes may also be present.

Oral Manifestations

- *Eroded area*—intraorally, there is presence of crops of vesicle which ruptures very rupturing leaving raw eroded areas.

Diagnosis

- *Clinical diagnosis*—crops of vesicle seen on flexor surface of hand with positive Nikolsky's sign.
- *Laboratory diagnosis*—acantholysis is more extensive as compared to other types of pemphigus. Characteristic feature of this disease in occasional intercellular bridges persist so that adjacent epithelial cells still adhere to each other. This gives classic description of the 'dilapidated brick wall' effect.

Management

- *Antibiotics therapy*—it is generally effective in this lesion. Topical antibiotics like clindamycin or erythromycin in improvement of lesion.
- *Soothing ointment*—soothing ointment like aluminum acetate will give some relief from symptoms.
- *Corticosteroids*—this should be used intermittently in this disease.

Epidermolysis Bullosa

It is a dermatological disorder in which bullae or vesicles occur on skin or mucous membrane surface spontaneously, shortly after minor trauma. There is defect in attachment mechanism of epithelial cells.

Classification

- *Epidermolysis bullosa simplex*
 - Generalized form
 - Localized form (Weber-Cockayne syndrome, recurrent bullous eruption of hands and feet)
- *Epidermolysis bullosa dystrophic, dominant.*
- *Epidermolysis bullosa dystrophic, recessive.*
- *Junctional epidermolysis bullosa* (Epidermolysis bullosa latalis, junctional bullous epidermatosis, Herlitz's disease)—it is severe form and many patient may die at birth.
- *Epidermolysis bullosa acqvista (acquired)*—it is similar to dystrophic form of the disease but usually with an adult onset. It is autoimmune rather than genetic in origin.

Clinical Features

Epidermolysis bullosa simplex

- *Age*—it is inherited as autosomal dominant trait and manifests at birth or shortly thereafter.
- *Sites*—it is characterized by formation of bullae or vesicle on the hands and feet at site of friction or trauma. The knees, elbows and trunk are rarely involved and nails are occasionally affected.
- *Healing*—when the blister heals within 2 to 10 days there is no resultant scarring or permanent pigmentation.

- *Prognosis*—the disease appears to improve at puberty and prognosis is good for normal life span.
- *Localized form*—the localized form is limited to hands and feet only and tends to exacerbate in hot weather.

Epidermolysis bullosa dystrophica dominant

- *Age*—the onset is at infancy and it may delay until puberty.
- *Sites*—the blister commonly develop on the ankles, knees, elbows, feet and head.
- *Appearance*—the initial lesions are vesicle or bullae. Healing results in scarring which is sometimes keloid in type.
- *Signs*—hair may be sparse (**Fig. 17-31**), while nails are usually dystrophic (**Fig. 17-32**) or absent with milia present.
- *Palmar-planter keratoderma* with hyperhidrosis also may occur with ichthyosis and sometimes hypertrichosis. In some cases finger nail may be lost.

Fig. 17-31: Sparse hair seen in epidermolysis bullosa patient.

Fig. 17-32: Dystrophic nails seen in epidermolysis bullosa.

Epidermolysis bullosa dystrophica recessive

- *Age*—it has onset at birth or very shortly thereafter.
- *Appearance*—it is characterized by formation of bullae spontaneously or at sites of trauma, friction or pressure (**Fig. 17-33**).
- *Sites*—the typical sites of involvement are the feet, buttock, scapula, elbows, finger and occiput.

Fig. 17-33: Vesicular lesion seen on thigh of patient in epidermolysis bullosa

- *Nikolsky's sign*—Nikolsky's sign is positive in this type of epidermolysis bullosa.
- *Aspiration*—the bullae contain a clear, bacteriologically sterile or sometime blood tinged fluid.
- *Signs*—when these bullae rupture or are peeled off under trauma or pressure, they leave raw, painful surface.
- *Healing*—the bullae heal by scar and milia formation which may result in a functional club-like fists.
- *Hair and nails*—the hair may be sparse, while the nails are usually dystrophic.
- *Finger*—there may be fusion of the finger resulting in mitten like deformity.

Junctional Epidermolysis Bullosa

It is extremely severe form of the dystrophic recessive form, which is incompatible with prolonged survival. It has onset at birth, absence of scarring, milia, pigmentation and death within three months of age. The bullae are similar to the recessive form but they develop simultaneously and sheets of skin may actually be shed.

Oral Manifestations

- *Epidermolysis bullosa simplex*—bullae of the oral cavity are reported in occasional cases of generalized epidermolysis bullosa, but teeth are not affected.
- *Epidermolysis bullosa dystrophica dominant*—bullae can occur in this type sometimes, oral milia can be seen but

teeth are unaffected. There is also gingival recession and reduction in depth of buccal vestibule.

- *Epidermolysis bullosa dystrophic recessive*
 - *Prodromal signs*—they may be preceded by the appearance of white spots or patches on the oral mucous membrane or by development of localized areas of inflammation. Vesicle and bullae formation may be induced by food having some degree of texture.
 - *Symptoms*—these bullae are painful especially when they rupture or when the epithelium desquamates (**Fig. 17-34**). Scar formation results in obliteration of sulci and restriction of the tongue movement. Hoarseness and dysphagia may occur as a result of bullae of larynx and pharynx.
 - *Signs*—esophageal involvement produces serious strictures.
 - *Teeth*—dental defects like rudimentary teeth, congenitally absent teeth, hypoplastic teeth and crowns denuded of enamel may be seen.

Fig. 17-34: Rupture bullae seen on upper lip in epidermolysis bullosa patient

- *Junctional epidermolysis bullosa*—oral bullae are frequently very extensive and because of their extreme fragility produce serious feeding problems. Severe disturbance in enamel and dentin formation of deciduous teeth also occur.

Diagnosis

- *Clinical diagnosis*—Nikolsky's sign is positive with vesicle and bullous formation on skin, leg, thigh and face. The diagnosis should be simple when the family history, reaction to trauma and the lesions appearing most profusely on the extremities are taken into consideration.
- *Laboratory diagnosis*—individual cells become edematous and show dissolution of organelles and tonofibrils with displacement of the nucleus to the upper end of cells.

Management

- *Sterile drainage*—large blisters should be pricked and the blister fluid released. Dressing, to minimize reaction may be helpful.
- *Antibiotics*—super infections should be treated with appropriate local or systemic antibiotics.
- *Plastic surgery*—mitten deformity of hand can be corrected with plastic surgery.
- *Lip lubricant*—this should be applied to prevent trauma to lip.

Dermatitis Herpetiformis

It is also called as 'Dühring-Brocq disease'. It is a rare, benign, chronic, recurrent dermatologic disease of unknown etiology.

Clinical Features

- *Age and sex*—it occurs between 20 to 55 years of age, with males affected at least twice as frequently as females.
- *Sites*—these occur most frequently on buttocks, extremities as well as on the face, scalp and sometimes, the oral cavity.
- *Symptoms and signs*—the first manifestation of the disease is usually pruritis and severe burning followed by the development of erythematous papules (**Fig. 17-35**), vesicles, bullae or pustules. The patient usually shows increased severity in summer months.

Fig. 17-35: Papular lesion seen on leg of patient in dermatitis herpetiform (Courtesy Dr Sanjay Pincha).

Oral Manifestations

- *Ulceration*—vesicles and bullae rupture very rapidly in oral cavity. This rupture of vesicle will result in formation of superficial ulceration.

Diagnosis

- *Clinical diagnosis*—ulcerative lesion in oral cavity in association with pruritis lesion present on extremities will give clue to the diagnosis.
- *Laboratory diagnosis*—the lesion shows accumulation of neutrophils and eosinophils in the dermal papillae. This will result in microabscess formation. Direct immunofluorescence staining is positive at the epidermal-dermal junction. Patient develops eosinophilia and sensitivity to halogens (chlorine, bromine, iodine and fluorine), both by patch test.

Differential Diagnosis

- *Pemphigus*—chronic course, epithelial tag on the borders of lesion, occurs in older patients.
- *Mucous membrane pemphigoid*—erosion, immunofluorescence, no necrosis, eye involvement, Tzanck test is negative.
- *Erythema multiforme*—acute onset, most commonly seen on the mucosa of lip, iris or target lesions, more frequent in young patients.

Management

- *Dapsone*—100-200 mg per day will give prompt relief.
- *Gluten free diet*—a gluten free diet may help to reduce or completely remove the disease.

Eosinophilic Ulcer of the Oral Mucosa

It is described in Chapter 22: Diseases of Tongue.

Angina Bullosa Hemorrhagica

It is the term used to describe benign and generally sub-epithelial oral mucosal blister filled with blood. Initially, it is called as *traumatic oral hemophlyctenosis*. The term angina bullosa hemorrhagica is given by Badham in 1967.

Etiology

- *Mild form of epidermolysis bullosa*—it has been suggested that it could represent a mild localized form of epidermolysis bullosa.
- *Minor trauma*—it can occur due to minor trauma due to hot, crispy and coarse food. Other factors which can cause minor trauma are periodontal therapy, dental injection of anesthetics.
- *Long-term steroid inhaler therapy*—in some cases, it is associated with long-term steroid inhaler therapy.

Clinical Features

- *Age and sex distribution*—it affects middle age or elderly people with no sex predilection.

- *Location*—it usually occurs on the soft palate.
- *Onset*—it is characterized by the rapid appearance of solitary blood filled blister (hemorrhagic bulla).
- *Symptoms*—patient may complain of apparent tightness (angina) in the area immediately before and during the formation of swelling.
- *Signs*—bulla may spontaneously discharge to leave area of erosion. It heals without scarring. Size may increase up to 1-3 cm in diameter.
- *Respiratory obstruction*—as this condition is acute in some cases, it may cause acute respiratory obstruction to the patient.

Diagnosis

- *Clinical diagnosis*—occurrence of hemorrhagic bulla with complaint of tightness will give clue to diagnosis.

Management

Patient should be given antiseptic mouthwash to control infection. As blister spontaneously ruptures and heals rapidly, no other treatment is required.

Common Syndromes

Stevens-Johnson Syndrome

It is the severe form of erythema multiforme with widespread involvement, typically involving skin, oral cavity, eyes and genitalia.

Clinical Features

- *Symptoms*—it commences with abrupt occurrence of fever, malaise, photophobia and eruptions on oral mucosa, genital mucosa and skin.
- *Cutaneous lesions*—cutaneous lesions are similar to erythema multiforme and are hemorrhagic, often vesicular or bullous.
- *Eye lesions*—it consists of photophobia, conjunctivitis, corneal ulcerations. Keratoconjunctivitis sicca has also been described and blindness may result, chiefly from recurrent bacterial infection.
- *Genital lesions*—genital lesions are reported to consist of non-specific urethritis, balanitis and vaginal ulcers.
- *Complications*—other reported complications are related to respiratory tract involvement such as tracheo-bronchial ulcerations and pneumonia.

Diagnosis

- *Clinical diagnosis*—erythema multiforme with skin, eye and genital lesion will aid in diagnosis.

Fig. 17-36: Stevens-Johnson syndrome showing extensive lesion on the soft palate.

Oral Manifestations

- *Symptoms*—oral mucous membrane lesions may be extremely painful and so, mastication becomes impossible.
- *Signs*—mucosal vesicles or bullae occur, rupture and leave a surface covered with thick, white or yellow exudates (**Fig. 17-36**).
- *Pharynx*—erosions of the pharynx are also common.
- *Lips*—lips may exhibit ulcerations with bloody crusting and are often painful.

Management

- There is no specific treatment for this, although in some cases, ACTH, cortisone and chlortetracycline have shown promising results.

Behcet's Syndrome

It is discovered by H. Behcet in 1937 as a triad of recurring oral ulcers, recurring genital ulcer and eye lesion.

Etiology

- *Immunological*—it is caused by immune complexes that lead to vasculitis of small and medium sized blood vessels. It has got strong association with certain HLA type. There may be inflammation of the epithelium caused by immunocompetent T-lymphocytes and plasma cells.
- *Environmental antigen*—it may be associated with environmental antigen such as bacteria (streptococci), viruses, pesticides and heavy metal.

Classification

- *Mucocutaneous*—oral, genital and skin lesions.
- *Arthritic*—arthritis, in addition to mucocutaneous lesions.

- *Neuro-ocular*—neurologic, ocular and mucocutaneous lesions.

Clinical Features

- *Age and sex*—it begins between 10 to 45 years of age, with a mean age of occurrence of 30 years. It is five to ten times more common in males.
- *Recurring oral ulcers*—it may be mild or may be deep, large scarring lesions and may appear anywhere on the oral and pharyngeal mucosa. They are painful lesions. They may range from several millimeters to a centimeter in diameter. These ulcers have erythematous borders and are covered by gray or yellow exudate.
- *Recurring genital lesions*—it includes ulcers of scrotum and penis in males and ulcers of labia in females. The genital ulcers are small and painful in females.
- *Eye lesions*—consist of uveitis, retinal internal edema and vascular occlusion, optic atrophy, conjunctivitis and keratitis.
- *Skin lesions*—these are generally small pustules or papules on the trunk or limbs and around the genital.
- *Arthritis*—arthritis is common. Affected joint is red and swollen.
- *CNS involvement*—it may occur and it may include brain stem involvement of cranial nerve and neurologic degeneration.
- *Others*—thrombophlebitis, intestinal ulceration, venous thrombosis, renal and pulmonary disease.

Diagnosis

- *Clinical diagnosis*—recurrent oral ulcerations at least 3 times in 12 month period, plus at least two of the following four manifestations:
 - Recurrent genital lesions.
 - Eye lesions including uveitis or retinal vasculitis.
 - Skin lesions including erythema nodosum, pseudofolliculitis and papulo-pustular lesions.
- *Laboratory diagnosis*—there is positive *Pathergy test* (cutaneous hypertrophy to intra-cutaneous injection or needle sticks (Pathergy) with the finding of pustule forming 24 hours after needle puncture).

Management

- *Topical and intralesional steroids*—oral mucosal lesions be treated with topical or intralesional steroids.
- *Severe cases*—patients with life threatening or slight threatening vasculitis are managed with combination of immunosuppressive drugs and systemic corticosteroids. Immunosuppressive drugs which used are cyclosporine, azathioprine and interferon alpha. Use of

above therapy will result in decreases in ocular and systemic manifestation.

- *Cyclosporine and colchicines combination*—cyclosporine and colchicine in combination with corticosteroids have also been shown to be useful in mucocutaneous and gastrointestinal manifestations.
- *Plasmapheresis*—this is used in emergency.

Reiter's Syndrome

It is a disease of unknown etiology and is considered as an important complication of non-gonococcal urethritis and is often acquired sexually. Reiter syndrome can also be found in HIV infected patient. Oral lesions occur in less than 5% to about 50% of the patients with the disease.

It consists of tetrad of:

- Urethritis.
- Arthritis.
- Conjunctivitis.
- Mucocutaneous lesions.

Etiology

- *Infectious agents*—it may be due to pleuropneumonia like organism. Variety of infectious agents like *bedsonia*, *mycoplasma*, *chlamydia*, virus, etc.
- *Staphylococci*—it can be associated with staphylococci and in that case, it is called as *staphylococcal scalded skin syndrome*.

Clinical Features

- *Age and sex*—it is totally confined to men, usually between the ages of 20 to 30 years.
- *Symptoms*—the disease begins abruptly with diffuse erythema and fever.
- *Signs*—large flaccid bullae are formed which contain a clear yellowish fluid. The bullae rupture very easily leaving large areas of skin devoid of superficial epidermis.
- *Genital findings*—the urethral discharge is usually associated with an itching and burning sensation.
- *Arthritis*—arthritis is often bilateral, symmetrical and usually polyarticular.
- *Conjunctivitis*—conjunctivitis is often so mild as to be overlooked.
- *Skin lesion*—the skin lesions consist of red or yellow keratotic macules which eventually desquamate.

Oral Manifestations

- *Sites*—it is seen on the buccal mucosa, lips and gingiva.
- *Appearance*—the lesions appear as painless, red, slightly elevated areas, sometimes granular or vesicular with a white circinate border.

- *Palatal lesions*—the palatal lesions appear as small, bright red, purpuric spots which darken and coalesce.
- *Tongue lesions*—lesions on the tongue closely resemble geographic tongue. They may be mistaken as recurrent aphthous ulcers.

Diagnosis

- *Clinical diagnosis*—the clinical finding of peripheral arthritis which last longer than 1 month in association with urethritis, cervicitis will diagnose this syndrome.
- *Laboratory diagnosis*—there is leukocytosis, and elevated ESR. Biopsy of lesion shows parakeratosis, acanthosis, and polymorphonuclear leukocyte infiltration of epithelium, sometimes with microabscess formation.

Differential Diagnosis

- *Geographic tongue and stomatitis*—no skin changes, no visceral lesions are seen.
- *Pustular psoriasis*—Auspitz's sign present.
- *Behcet's syndrome*—no urethritis, aphthae with red halo.
- *Stevens-Johnson syndrome*—acute appearance, more severe clinical course, no arthritis or urethritis.
- *Benign mucosal pemphigoid*—blister formation, no urethritis, found in older patients.

Management

- *Spontaneous remission*—many patients undergo spontaneous remission.
- *Antibiotics*—in case symptomatic patient, doxycycline or minocycline may be given.
- *Analgesics*—nonsteroidal anti-inflammatory drugs are given to manage arthritis.
- *Immunosuppressive agents*—immunosuppressive agents like azathioprine and methotrexate are given in cases of most resistant cases.

Miscellaneous Oral Ulcers

Oral Ulcers Secondary to Cancer Chemotherapy

It may be due to direct effect on replication and growth of oral epithelium by interfering with nucleic acid and protein synthesis and leading to thinning and ulceration of oral mucosa, e.g. by methotrexate, or it may act indirectly by depression of bone marrow and immune response leading to bacterial, viral and fungal infections.

Clinical Features

- *Hair*—alopecia due to arrest of mitosis of the rapidly germinating hair root.
- *Stomatitis*—stomatitis occurs with diffuse inflammatory changes developed in mucosa.

- **Blebs**—distinct blebs or whitish areas result from decreased cellular division and retention of squamous cells.
- **Symptoms**—there is also burning sensation in the oral cavity with mucosal erosion.
- **Appearance**—in subsequent weeks, surface layer is lost and thin erythematous mucosa is present. Focal areas ulcerate and then become covered with tan yellow fibrous exudates (Fig. 17-37).

Fig. 17-37: Ulceration seen in palate after patient is given chemotherapy for the malignancy,

Management

- **Topical anesthetic**—topical anesthetic such as elixir of diphenhydramine or lidocaine combined with milk of magnesia.
- **Tetracycline suspension**—oral suspension of tetracycline which is used as mouthwashes and then swallowed.

Diffuse Gangrenous Stomatitis

It occurs in extremely debilitated patients, advanced diabetes, uremia, leukemia, blood dyscrasias, malnutrition state and heavy metal poisoning. It is sensitive painful oral lesions and very unpleasant odor. They are multiple and surrounded by thin inflamed margins. It is covered by dirty gray to yellow pseudomembrane that can readily be removed. It may be elliptical, linear and angular. There is tender to painful cervical lymphadenopathy. It is managed by systemic penicillin and hydrogen peroxide rinse.

Differential Diagnosis of Oral Ulcers

Short-Term Ulcers (Disappear within 3 weeks)

- **Ulcers secondary to systemic diseases**—patient history.
- **Ulcers from odontogenic infections**—identify the affecting tooth. Presence of sinus, gutta percha digital pressure in involved tooth or alveolus causes drops of pus to be expressed from the opening in ulcers.
- **Traumatic ulcer.**
 - Recurrent aphthous ulcers and recurrent herpes infection.

Persistent Ulcers (Longer than 3 weeks)

- **Metastatic tumor**—occurs in lower half of oral cavity, primary tumor elsewhere.
- **Low grade mucoepidermoid carcinoma**—not so common, occurs in posterolateral region of hard palate.
- **Gumma**—Mostly in midline of palate, rubbery consistency and serological finding.
- **Chancre**—it is reddish brown with copperhead colored halo.
- **Necrotizing sialometaplasia**—uncommon benign ulcerative inflammatory process of minor salivary glands found in posterior hard palate.
- **Keratoacanthoma**—seen in lower lip, rapid growth.
- **Major aphthous**—severe pain, inflammatory borders.

Introduction

Pain and fear of pain continues to be the strongest motivation for people to seek dental care. Pain is a personal experience of the sufferer that cannot be shared and it wholly belongs to the sufferer. The head and face are subjected to chronic persistent or recurring pains more often than any other portion of the body. The dentist's responsibility in managing orofacial pain is twofold, first is the diagnosis, and second is the therapy.

The most frequent source of orofacial pain is dental disease and it has been estimated that toothache is a major health problem. Many conditions manifest as only orofacial pain with no other associated signs or symptoms. It has been clear that successful diagnosis of orofacial pain depend on (Fig. 18-1).

- *History*—an accurate and detailed history of the pain.
- *Clinical examination*—a detailed clinical examination of the face and associated organs.
- *Knowledge*—thorough knowledge of those conditions which may produce orofacial pain.

Pain is derived from word 'poine' meaning payment or penalty, which certain segments of our religious heritage have translated as being synonymous with punishment.

Fig. 18-1: Diagnosis of pain should be done with the help of three factors.

Severity of pain is a measure of the suffering it induces than the actual perception of the noxious stimulation. Low intensity pain may arise from very serious causes, whereas maximum intensity pain such as *tic douloureux* may arise from imperceptible causes.

Definition

- By IASP (*international association for study of pain*)—it is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in term of such damage.
- It is an unpleasant emotional experience initiated by noxious stimuli and transmitted over a specialized neural network to the central nervous system, where it is interpreted as such.
- It is more or less a sensation of discomfort, distress or agony resulting from the stimulation of specialized nerve endings.
- It is a distressing sensation elicited by noxious stimuli of sufficient intensity acting on nerve endings.

Types and Nature of Pain

Pain may be judged subjectively or objectively. Subjective evaluation depends on the patient's description of the complaint. Objective evaluation relates to what the pain does to the patient physically as seen by change in vital signs, skin color, pupil size, and muscle effects.

There is definite relationship between intensity and duration of pain. The higher the intensity of the pain, the shorter the period of time that can be tolerated by the sufferer. Accordingly, low intensity pain can be sustained for upto several hours whereas maximum intensity pain can be tolerated just for few seconds. The higher the intensity of the pain, more likely it is to be intermittent.

Types According to Pain Intensity

- *Mild pain*—can be controlled by the use of simple analgesics.
- *Moderate pain*—can be controlled with narcotic analgesics.
- *Severe pain*—cannot be controlled by analgesics, but requires either elimination of the cause or interruption of the pain pathways.

According to Temporal Relationship and Duration

- *Intermittent*—pain of short durations and separated by wholly pain-free period.
- *Continuous*—pain of longer duration.
- *Protracted*—a painful episode that lasts for several days is usually described as protracted.
- *Intractable*—pain that does not respond to therapy.
- *Recurrent*—two or more similar episodes of pain.
- *Remission*—the pain-free interval between recurring episodes is called as remission.
- *Periodic*—pain that is characterized by regularly recurring episode is said to be periodic.

According to Qualities of Pain

- *Steady pain*—it flows as an unpleasant sensation.
- *Paroxysmal pain*—sudden attack or outburst of pain.
- *Bright pain*—stimulating quality.
- *Dull pain*—it has got depressing quality.
- *Itching*—it is a sub-threshold pain and usually is not described as pain at all. It may have a warm or even burning quality and can become intractable.
- *Pricking*—it has a sharp intermittent character of short duration like a pin pricking the skin.
- *Stinging*—it is more continuous and of higher intensity and quality.
- *Burning*—it gives a feeling of warmth or heat, when short and intense, it may have electric shock like feeling.
- *Throbbing*—pulsatile pain is timed to cardiac systole.
- *Aching*—it is the descriptive term most frequently used unless the pain is overshadowed by one of the other characteristic sensations.

According to Onset

- *Spontaneous*—if the pain occurs without being provoked.
- *Induced*—when some provocation causes the painful sensation.
- *Triggered*—when evoked response is out of proportion to the stimulus.

According to Pain Localization

- *Localized*—if the patient is able to clearly and precisely define the pain to an exact anatomical location.
- *Diffuse*—it is less well defined and somewhat vague and variable anatomically.
- *Radiating*—rapidly changing pain
- *Lancinating*—a momentary cutting exacerbation
- *Spreading*—gradually changing pain
- *Enlarging*—if pain progressively involves adjacent anatomical areas, it is called as enlarging.
- *Migrating*—if it changes from one location to another, the pain is described as migrating.

Neurophysiology of Pain

- *Structure of nerve*—nerve is a cord-like structure that conveys nervous impulse. It consists of a connective tissue sheath called as *epineurium*, which enclose bundles of nerve fibers, each bundle being surrounded by its own connective tissue sheath called as *perineurium*. Within each bundle the nerve fibers are separated by interstitial connective tissue called as *endoneurium* (Fig. 18-2).

Fig. 18-2: Structure of nerve showing endoneurium and perineurium.

- *Structure of nerve fiber (Fig. 18-3)*—an individual nerve fiber consists of a central bundle of neurofibrils in a matrix of nerve protoplasm, called *axoplasm*, enclosed in a thin nerve tissue plasma membrane called *axolemma*. Each nerve fiber is covered by cellular nerve tissue sheath called as *neurolemma*. Some of these fibers also have a layer of fatty nerve tissue called the *myelin sheath*. Fibers with myelin sheath form the white nerve and those without the myelin sheath form the gray nerve.

Fig. 18-3: Structure of nerve fiber diagrammatic representation.

- **Nodes of Ranvier**—constrictions called as *nodes of Ranvier* (**Fig. 18-4**) occur in myelinated nerves at intervals of about 1 mm. These nodes are caused by the absence of myelin material so that only neurolemma covers the nerve fiber. Those situated in the white substance are myelinated, whereas those in the gray substance are non-myelinated.

Fig. 18-4: Nodes of Ranvier.

- **Neuron**—the structural unit of the nervous system is the nerve cell or *neuron*. It is composed of a mass of protoplasm called nerve cell body (*perikaryon*), which contains a spherical nucleus (*karyon*) and gives off one or more processes.
- **Dendrites and axons**—protoplasmic processes from the nerve cell body are called as *dendrites* and *axons*. Dendrite (from the Greek word *dendron*, meaning tree) is a branched process that conducts an impulse towards the cell body (**Fig. 18-5**). An axon or axis cylinder is the central core that forms the essential conductor in a nerve cell and is an extension of cytoplasm from nerve cells.
- **Synaptic junction**—nervous impulses are transmitted from one neuron to another only at a synapse or a synaptic junction, where the processes of two neurons are in close proximity. All the afferent synapses are located within the gray substance of the CNS. Most of the primary synapse of nerve fibers, which carry pain, are located in the substantia gelatinosa of the cord and brainstem. The synapses that occur outside the CNS are those of efferent pre- and post-ganglionic autonomic fibers and these are located in the sympathetic ganglion.
- **Reflex arc**—some neural circuits are simple, i.e. an impulse from a sensory receptor being conveyed by the primary

Fig. 18-5: Dendritic of nerve cell body.

afferent neuron to a synapse in the CNS with a secondary internuncinal neuron, which in turn synapses with a third efferent motor neuron, which will conduct the impulse peripherally to an effector organ such as a muscle. Such circuit formed by a chain of neurons in which stimulation is followed by an immediate and automatic response is called as *reflex arc*. The synapsing of a neuron with several other neurons is known as *convergence*. At the synapse, there may be cumulative effect, called *summation*. Intensification of response is known as *facilitation* and suppression of response is called as *inhibition*.

Types of Nerve Cells

Depending on the Number of Axons

- Unipolar
- Bipolar
- Multipolar

Depending on their Location and Function

- **Afferent neuron**—it conducts impulse toward the CNS.
- **Efferent neuron**—it conducts nervous impulse peripherally (**Fig. 18-6**).
- **Internuncinal neurons or interneuron**—it lies wholly within the CNS (**Fig. 18-7**).
- **Sensory or receptor neuron**—they are afferent in type, receive and convey impulses from receptor organs.
- **Motor or effector neurons**—they are efferent and convey nervous impulses to produce muscular or secretory effects.

- *Preganglionic neuron*—it is an autonomic efferent neuron whose nerve cell body is located in the CNS and terminates in an autonomic ganglion.
- *Postganglionic neuron*—it has its nerve cell body in the ganglion and terminated peripherally.

Fig. 18-6: Afferent and efferent nerve.

Fig. 18-7: Interneuron present in the brain.

Sensory Receptors

Sensory nerve fibers that respond to physical stimuli and convert them into nervous impulses for conduction towards the CNS are called sensory receptors.

There are three types:

Exteroceptors

They are stimulated by external environment and are thus located so as to become exposed to the external environment. Most impulses arising from these are sensed at conscious level. For example—

- *Merkel's corpuscles*—tactile receptors in submucosa of tongue and oral mucosa.
- *Meissner's corpuscles*—tactile receptors of skin.
- *Ruffini's corpuscles*—pressure and warmth receptors.
- *Krause's corpuscles*—cold receptors.
- *Free nerve endings*—perceive superficial pain and tactile sensations.

Interoceptors

They are located in and transmit impulses from the cavities of the body. Most impulses arising from these receptors are involved in involuntary functions of the body and are below conscious levels. For example—

- *Pacinian corpuscles*—concerned with perception of pressure.
- *Free nerve endings*—perceive visceral pain and other sensations.

Proprioceptors

They give information concerning the presence, position and movement of the body. For examples—

- *Muscle spindles*—mechanoreceptors found between the skeletal muscle fibers which respond to passive stretch of the muscle.
- *Golgi tendon organs*—mechanoreceptors in tendons of muscle.
- *Pacinian corpuscles*—receptors concerned with the perception of pressure.
- *Pressoreceptors*—receptors in periodontal ligament.
- *Free nerve endings*—perceive deep somatic pain and other sensations.

Pain Conduction

The conduction of an impulse by a nerve depends on the electrical potential that exists across the nerve membrane. The transmission of impulse is brought about by the flow of current across the membrane during the transition of the nerve from the resting to the active state (Fig. 18-8).

Fig. 18-8: Pain conduction showing resting stage, depolarization and repolarization.

Resting state

- *Ion concentration*—when the nerve is at rest, greater amount of anions (-ve) are present inside the cell membrane, whereas an equal number of cations (+ve) are gathered outside the membrane. The positively charged potassium ions are concentrated inside, while sodium and chloride ions are concentrated outside the membrane.
- *Creation of potential electrical difference*—the difference in respective ion concentrations across the nerve membrane

creates a potential electrical difference between the inside (negative) and outside (positive).

- *Resting potential*—thus, an unstimulated nerve at rest will have a resting potential, during which the membrane is said to be polarized with the inside being electrically negative relative to the outside. The resting potential of the nerve is maintained by the relative permeability of the cell membrane to potassium and its relative impermeability to sodium ions. Positively charged potassium ions are retained by the electrostatic attraction of the negatively charged nerve membrane. Chloride remains outside the nerve membrane because of the opposing electrostatic influence, forcing outward migration.
- *Sodium pump*—the maintenance of the resting potential is mainly because of an active mechanism called as 'sodium pump', which moves sodium from the area of lesser concentration inside the nerve to that of greater concentration outside. Because of greater concentration outside and the lesser concentration inside the nerve, the sodium ions tend to diffuse back across the membrane into the nerve while being pumped out. This pumping action controls the concentration of sodium on both sides of the membrane and thus maintains it in a polarized state. Thus, both concentration and the electrostatic gradients for sodium favor its inward movement, but, relative impermeability of the nerve during the resting state prevents the massive influx of this ion.

Depolarization

- *Activation of membrane by stimulus*—when a stimulus of sufficient intensity is applied to the nerve, the membrane is activated by the increased permeability of sodium, which diffuses through the membrane into the nerve cell.
- *Sodium diffusion*—the marked increase in the diffusion of sodium into the cell is followed by the passage of potassium out of the cell. This action is said to abolish the resting potential and depolarize the membrane.
- *Liberation of acetylcholine*—as the nerve is stimulated; there is a rapid passage of sodium into cell and a slower passage of potassium out of it. The alteration in permeability of cell membrane after the stimulus is a result of liberation of transmitter substance, acetylcholine, at the site of stimulation.

Repolarization

- *Change in permeability*—following depolarization, the permeability of the nerve membrane to sodium is again decreased, while the high permeability of potassium is restored.

- *Restoration of electrochemical equilibrium*—potassium moves freely out of the cell, thereby restoring the original electrochemical equilibrium and resting potential. Movement of both sodium ions into the cell during depolarization and potassium ions out of the cell during repolarization are both passive actions since these ions move along the concentration gradient.
- *Return of resting potential*—the return of resting potential occurs within 3 to 4 seconds after the initial stimulation.

Theories of Pain

Specificity Theory

In 1644, Descartes postulated this theory that pain system is a straight channel from the skin to brain. It was thought that this specific pain system carried message from the receptors to pain center in the brain.

Doctrine of Specific Nerve Energies

In 1842, Muller postulated this theory. This theory states that the brain receives information about external objects only from sensory nerves.

Pattern Theory

It was proposed by Goldscheiders. He emphasized that stimulus intensity and central summation are the critical determinants of pain. He proposed that the large cutaneous nerve fibers comprise a specific touch system whereas the small fibers converge on the dorsal horn cells, summate their input and transmit a pattern to the pain receptors which perceives the pain.

Peripheral Pattern Theory

A recent variation of pattern theory has been proposed by Weddell (1955) and Sinclair (1955) and it is called as peripheral pattern theory. This theory holds that all cutaneous qualities which are produced by spatiotemporal patterns of the nerve impulse rather than by the modality specific transmission route. All fiber endings are alike and pain is produced by intense stimuli to non-specific receptors.

Central Summation Theory

Livingstone suggested a specific neural mechanism, in which, with intense pathologic stimulation of the body, sets up a reverberating circuit in spinal internuncial pools that can be triggered by non-noxious stimuli leading to abnormal volleys that can be interpreted centrally as pain.

Sensory Interaction Theory

It is stated by Noordenbos and it states, the large fiber-pain inhibitory and small fiber-pain contributory, concepts with the two systems being in balance with one another. A decrease in the ratio of large to small fiber activity results in central summation and an increase in pain.

Gate Control Theory

This is the most accepted theory. It proposes that (Figs 18-9A and B):

- *Neural mechanism in dorsal horns*—a neural mechanism in the dorsal horns of spinal cord (substantia gelatinosa) acts as a gate that can increase or decrease the flow of impulse from the periphery of the body to the brain before pain perception can be evoked. Afferent input is subject to the modulation of the gate before it can activate the central transmission cells and evoke pain perception as a response.
- *Alpha, delta and c fibers*—more active large (A-alpha and A-delta) fibers and the less active smaller (A-delta and C) fibers determine the degree to which the gate modulates sensory transmission. Activity of large fibers tend to inhibit transmission (close the gate) and small fiber activity tends to facilitate transmission (open the gate).
- *Impulse from brain*—it was further proposed that the control over transmission is affected not only by the gate mechanism but also by the impulse descending from the brain. Hence, the signal that triggers the system responsible for pain perception and patient response occurs when the T cell output reaches a certain critical level.

Measurement of Pain Intensity

- *Verbal communication*—this is communicated to you from the patient.
- *Visual analogue scale*—pain intensity can be measured by visual analogue scale. This scale consists of 10 cm lines. On this scale, there is marking from 0 to 10. 0 means no pain and 10 means very severe pain. Patient is asked to mark the line which represent pain.
- *McGill pain questionnaire*—this is useful in evaluation of pain. This questionnaire consists of 20 groups with 78 types of pain. In these groups, 1 to 10 is designed for assessment of sensory character, group 11 to 15 to assess affective character and from group 16 to 20 assess evaluative character of pain (Table 18-1).
- *Disability status*—this is very important in assessing the pain. Disability is lack of ability to function normally, physically and mentally.

A

B

Figs 18-9A and B: Gate control theory—a diagrammatic representation.

- *Multiaxial assessment of pain*—this includes 61 item questionnaires which measure adjustment to pain from cognitive behavioral pattern. This will help in getting profile of the patient. Patient profile can be dysfunctional (low activity with higher degree affective distress), distressed (patient think that other are supportive of their problems) and adaptive copers (patient with high level of social support).

Table 18-1: McGill pain questionnaire

Group 1	Burning	Vicious
Flickering	Scalding	Killing
Quivering	Searing	
Pulsing	Group 8	Group 15
Throbbing	Tingling	Wretched
Beating	Itchy	Blinding
Pounding	Smarting	
Group 2	Stinging	Group 16
Jumping	Group 9	Annoying
Flashing	Dull	Troublesome
Shooting	Sore	Miserable
Group 3	Hurting	Intense
Pricking	Aching	Unbearable
Boring	Heavy	
Drilling	Group 10	Group 17
Stabbing	Tender	Spreading
Lancinating	Taut	Radiating
Group 4	Rasping	Penetrating
Sharp	Splitting	Piercing
Cutting	Group 11	Group 18
Lacerating	Tiring	Tight
Group 5	Exhausting	Numb
Pinching	Group 12	Drawing
Pressing	Sickening	Squeezing
Gnawing	Suffocating	Tearing
Cramping	Group 13	Group 19
Crushing	Fearful	Cool
Group 6	Frightful	Cold
Tugging	Terrifying	Freezing
Pulling	Group 14	Group 20
Wrenching	Punishing	Nagging
Group 7	Grueling	Nauseating
Hot	Cruel	Agonizing
		Dreadful
		Torturing

- *Graded chronic pain severity scale*—this is given by Dworkin and LeReschae. It has got four grade of disability.
- *Quantitative sensory testing*—quantitative testing modalities include thermal, mechanical and electrical stimuli.

Classification of Orofacial Pain

- *Neuropathic pain*—orofacial pain associated with nerve dysfunction or abnormalities of the peripheral nerve. In this type pain is caused by the lesions affecting the intracranial but extra-pontine or extra-medullary portion of cranial nerves V, VII, IX, and X are classified as neuropathic
 - *Paroxysmal pain*
 - Trigeminal neuralgia
 - Geniculate neuralgia
 - Glossopharyngeal neuralgia
 - *Non-paroxysmal pain*
 - *Trauma*—pain occurring after trauma to nerve.
 - *Viral*—nerve getting involve due to virus.

- *Neoplasm*—neoplasm of the parotid gland, nasopharynx and acoustic neuroma may cause pain.
- *Non-neuropathic pain*—this type of pain involves nerves likely to be associated with the pain. It is subdivided into:
 - *Central origin*—this type of pain is caused by the lesions affecting the cord (central nervous system) is referred to as non-neuropathic pains of central origin.
 - *Neuronal damage*—pain results from neuronal damage in CNS.
 - *Phantom limb pain*—phantom limb pain and causalgia (a persistence burning sensation resulting from peripheral nerve trauma associated with various other phenomenon and curable by stellate ganglion block).
 - *Brain tumor and central lesion*—tumor, vascular lesion and other destructive lesions of the brain stem, pons, thalamus and cerebrum should be considered in the diagnosis of chronic orofacial pain.
 - *Other causes*—like thalamic syndrome of Dejerine and Roussy, tertiary neurosyphilis and multiple sclerosis.
- *Extra-neural origin*
 - *Dental*—this includes dental caries, exposed dentin and cementum, pulpal and periapical disease, periodontal disease, pericoronitis, impacted food, ANUG, faulty restorations, fractured teeth, traumatic occlusion, tooth eruption and exfoliation, unerupted and impacted teeth, retained root, dental cyst, post-surgical pain, post-injection pain, and other direct trauma to the teeth and aerodontalgia.
 - *Alveolar and adjacent tissue origin*—dry socket, sinusitis, various neoplastic and non-neoplastic, osteolytic lesions, Paget's disease, multiple myeloma etc.
 - *Musculoskeletal*—TMJ arthritis, TMJ myofascial dysfunction, myositis, muscle spasm and trismus, cervical muscle spasm, osteoarthritis, arthralgia of the cervical spine and tension headache.
 - *Vascular*—vascular headaches including migraine and cluster headache, toxic and metabolic vascular headache, hypertensive vascular changes, arterial diseases such as aneurysms, emboli, cranial arteritis (including giant cell arteritis, polymyalgia and immune arteritis), thrombophlebitis and carotidynia.
 - *Pain referred from outside the orofacial area*—otitis media, inflammatory or neoplastic diseases of the ear, diseases of major salivary glands (calculus, cyst and tumor), lesions of nasal and sinus mucosa, myocardial ischemia which may all cause pain in the orofacial area, often at some distance from the focus of disease.

Table 18-2: Second classification of orofacial pain

Superficial pain

- Cutaneous pain
- Mucogingival pain

Deep pain

- *Odontogenic pain*
 - Pulpal pain
 - Periodontal pain
- *Musculoskeletal pain*
 - *Muscle pain*
 - Local muscle soreness
 - Muscle splinting pain
 - Neoplastic myofacial pain
 - Muscle spasm pain
 - *Temporomandibular joint pain*
 - Disc attachment pain
 - Retrodiscal pad pain
 - Capsule pain
 - Arthrography pain
 - *Soft connective tissue pain*
 - Osseous pain
- *Vascular pain*
 - Atypical facial neuralgia
 - Cranial arteritis
- *Visceral pain*
 - True visceral pain
 - Reflex sympathetic dystrophy

Neurogenous*Traumatic neuroma pain*

- *Neuritis pain*
 - peripheral neuritis
 - herpes zoster
- *Neuralgia pain*
 - Idiopathic neuralgia
 - Symptomatic neuralgia

Psychogenic pain

- Psychogenic intensification pain
- Conversion hysteria pain
- Delusional pain

- *Pain of unknown nature*—pain that arises outside the peripheral nerve and only affects the nerves and their receptors secondarily (e.g. pain of dental caries, periodontal disease and mouth ulcers).

Acute Pain

Acute pain may be considered to be a protective mechanism for the body, by stimulating the sympathetic nervous system, is often accompanied by the automatic signs of stress and anxiety. It serves as a diagnostic value to the clinician in determining the nature and site of the disturbance.

Chronic Pain**What is chronic pain?**

It is persistent of pain after healing. Pain of more than 6 months duration may be considered as chronic pain.

Table 18-3: Third classification of orofacial pain

Typical neuralgias

- Trigeminal
- Glossopharyngeal
- Geniculate
- Superior laryngeal
- Post-herpetic

Atypical neuralgias

- Migraine
- Spheno-palatine neuralgia
- Migranous neuralgia
- Ciliary's neuralgia
- Petrosal neuralgia
- Carotodynia
- Cluster headache

Typical facial pain

- *Pain of extra-cranial origin*
- Dental disease
- Ocular disease
- Ear, nose and throat disease
- Salivary gland disease
- TMJ syndrome
- Musculoskeletal disorders of the head and neck
- Cranial arteritis
- Thyroid disease
- Angina pectoris
- *Pain of intra-cranial origin*
- Trigeminal neuropathy
- Tumor of middle cranial fossa and Gasserian ganglion
- Cerebellopontine angle tumor
- Thalamic central pain syndrome
- Trigeminal neuralgia in multiple sclerosis

Atypical facial pain

- It refers to mixed group of conditions diagnosed by exclusion of other typical patterns of facial pain. The conditions are characterized by poorly localized, deep, constant discomfort which is non-anatomic, non-dermatomal and is frequently described by the patient in vague terms which gives psychogenic basis for the disorder.

Table 18-4: Fourth classification of orofacial pain

Acute

- *Dental*—pulpitis, cracked tooth syndrome
- Gingivitis, periodontitis, pericoronitis
- *Mucosal*—various causes of ulceration
- *TMJ*—traumatic acute dysfunction
- *Maxillary sinus*—sinusitis and carcinomas
- *Salivary gland*—acute sialadenitis
- *Ear*—otitis externa and media
- *Tonsils*—quinsy and carcinoma
- *Referred*—cardiac, angina, cervical spondylitis

Chronic

- *Neuropathic*—trigeminal and post-herpetic neuralgia
- *Nociceptive*—cancer, osteoarthritis, rheumatoid arthritis
- *Chronic and recurrent idiopathic orofacial pain*—TMJ dysfunction syndrome, atypical facial pain, atypical odontalgia, oral dysesthesia, tension headache, migraine, facial migranous neuralgia.

Chronic pain does not serve any apparent biological function and is psychologically destructive. It is not self-limiting and appears to be permanent. Nowadays, any persistent pain more than 3 months of duration is called as chronic pain. Merskey et al described chronic pain as 'persistent pain that is not amenable, as a rule to treatment based on specific remedies or to the routine methods of pain control such as non-narcotic analgesics'.

Pathophysiology

- *Inflammatory origin*—many orofacial pains of chronic are inflammatory in origin. The inflammatory response to tissue damage, results in the production of pain, edema, local increase in temperature, redness and loss of function.
- *Neuroplasticity*—neurons are capable of altering the structure and function in response to stimuli. This will result in new stimulus response relationship.
- *Reduction in stimulation threshold*—this will result in activation of neurons without noxious stimulus.
- *Alteration in temporal pattern*—due to this transient stimulus may lead to sustained burst of activity.
- *Greater response*—there is increase in general response of motor neurons. This will result in more response to noxious stimuli.
- *Expansion of receptive field*—this will result in wider area may get involve with the stimuli.

Clinical Manifestation

- *Hyperalgesia*—changes in CNS result in the clinical manifestation of hyperalgesia. Hyperalgesia is characterized by spontaneous pain, decreased pain threshold and an increased magnitude of perceived pain for any given stimulus.
- *Allodynia*—there is pain due to stimulus that does not normally cause pain.
- *Psychosocial disturbance*—patient suffers from the depression, anxiety, and social isolation.
- *Dysfunction*—due to chronic pain normal activity of patient is decreased.

Superficial Pain

Superficial pains have a bright, stimulating quality and can be correctly located by the patient so that he is aware of precisely where it hurts. He is able to describe the location of the pain with anatomical accuracy and thus the site of pain and site of origin are identical.

Superficial pain is primary hyperalgesia, i.e. the structure is painful owing to lowered threshold from local cause. The reaction is proportional to the intensity of the stimulus; it lasts as long as the stimulus and there is no reference to pain to other structures.

Types and Clinical Features

- *Cutaneous pain*—it is characterized by pricking or burning sensation.
 - *Pricking pain*—pricking pain will occur if the stimulus is slight and short duration.
 - *Stinging pain*—if the stimulation is slight but sustained or rapidly repeated a slight stinging sensation is felt.
 - *Burning pain*—severe stimulation can cause burning pain.
- *Mucogingival pain*—it differs from cutaneous pain as it does not show the typical pricking; burning pattern of cutaneous pain. The reason for this is that the number of thick fibers innervating the oral mucosa is negligible as compared to that of skin. The entire oral mucosa feels a stinging and burning sensation. Pain arising from the oral tissues can be precisely located by the patient. Mucogingival pain can be generalized, isolated, referred and neurogenous.
 - *Generalized mucogingival pain*—it is caused by following factors:
 - *Local causes*—irritating effect of substances like food, liquid, mouth washes, dentifrices, and medications. Generalized mucogingival pain may occur due to abrasive effect of excessive rubbing of the tongue and cheek. In this, various signs of hyperemia, inflammation can be seen at the site of pain.
 - *Local infection*—widespread local infection of mucogingival tissue can cause generalized superficial somatic pain. Signs of inflammation and ulceration make the cause of pain obvious.
 - *Glossodynia, burning mouth and burning tongue*—it may cause steady, continuous typical superficial somatic pain. The location of pain corresponds to the area of greatest movement. Secondary infection of the irritated tissue may complicate the symptoms. Xerostomia may also cause this condition.
 - *Massive superficial injury*—traumatic effect from mechanical, thermal or chemical cause such as scalding with hot foods or liquids, excessive smoking or use of tobacco, abrasion from tooth brushes, etc. may cause pain.
 - *Allergic response*—it includes stomatitis medicamentosa and stomatitis venenata. They may produce rather generalized mucogingival pain. These conditions are usually accompanied by the objective sign of tissue change and the cause can be known by careful history taking.
 - *Pregnancy*—pregnancy and perhaps the ingestion of oral contraceptive drugs cause oral manifestations which may cause pain.

- *Systemic disease*—systemic diseases may cause oral manifestations that affect the mucogingival tissues causing generalized superficial somatic pain, for example, nutritional deficiency, intoxication, anemia, other blood dyscrasias, pellagra, diabetes, and pemphigus.
- *Isolated mucogingival pain*—various isolated lesions, like herpes simplex, oral ulcerative lesion of aphthous stomatitis, ulcer form dental appliances, can cause isolated pain in the mucogingival tissue. Whenever the periosteal and osseous structures become involved, pain of mixed quality is generally expected.
- *Referred mucogingival pain*—according to central excitation theory, the input of deep pain impulses may stimulate other neurons that mediate pain causing referred pain. If that neuron mediates superficial pain impulse then referred pain will have characteristics of superficial somatic pain. Thus, deep pain may secondarily induce mucogingival pain. Referred pain in the mucogingival tissue may occur as a direct result of deep pain source such as toothache, earache, sinusitis, temporomandibular arthralgia and vascular pain.
- *Neurogenous mucogingival pain*—neurogenous pains present clinical characteristics simulating those of the superficial somatic pain. For example, painful neuroma, neuritic pain, neuralgia pain.

Deep Pain

Sensory innervations of the deeper structures of the body supply the cortex with constant inflow of information regarding all internal functioning of the body. Deep pain has a dull, depressing quality. Deep pain is less accurately localized by the patient and the patient's anatomical description of where he feels the pain may be quite diffuse. Deep pain may not be proportional to the stimulus. Some deep pains respond rather faithfully to stimulus but not as faithfully as superficial pain. One of the clinical characteristic of the deep pain is central hyperexcitability. Deep pain input tends to cause referred pain, secondary hyperalgesia, localized autonomic effects and secondary myospasm activity.

Pains of Dental Origin

Dental pain is usually described as an aching sensation; sometimes throbbing, and when severe, may have a burning quality.

- *Pulpal pain*—pulpal pain may be classified as acute, chronic, and recurrent or mixed with periodontal element. Pulpal pain may resolve, or become chronic.
- *Acute pain*—the cause of acute pulpal pain is noxious stimulation of the pulpal receptors. This type of pain

is not completely localized by the patient. The cause for acute dental pain is deep caries, erosion, fracture or splitting tooth. This will help in identification of the offending tooth. As soon as pulp is exposed, it becomes painful in contact with saliva or air. The pain threshold of all deep receptors and nerve fibers that mediate pain is lowered by sustained hyperemia or inflammation. Thus, dental pulp that is hyperemic or inflamed is hypersensitive to all stimuli including electric stimulation, thermal shock, probing and percussion. As the inflammatory process progresses spontaneous toothache may occur without any outside provocation. Acute pulpal pain may range from occasional hypersensitivity caused by sweet and other minor stimulants to spontaneous violent throbbing toothache of intolerable intensity. It may be induced by any type of irritants or be wholly spontaneous. It may be increased by both heat and cold or increased by heat and relieved by cold. Pain frequently occurs at night when the patient lies down or when the patient leans down, most probably because of an increase in blood pressure. The difference between a hyperemic pain caused by thermal reaction and acute pulpitis is that in acute pulpitis the pain does not necessarily resolve when the irritants are removed but continue to ache for few minutes and possibly for hours. The usual relief for advanced acute pulpitis is cold water.

- *Chronic pain*—injured pulpal tissue may progress from an acute to chronic inflammatory phase. It results from a continued low grade infection. When chronic pulpitis occurs, pain response changes from extremely variable character of acute pulpal pain to milder and less variable vague discomfort that may not be described as pain at all. Tooth may become symptomless.
- *Toothache from non-dental cause*—pain referred to teeth from inflamed nasal mucosa, nonspastic myofacial pain especially involving temporalis and masseter muscle, myofacial pain-dysfunction syndrome, pain of the heart muscles as a symptom of cardiac disease. Neuritic pain such as those involving the maxillary teeth from inflammatory involvement of the superior dental plexus by the disease of the antrum and from neuritic conditions of the inferior alveolar nerve.
- *Periodontal pain*—the receptors of the periodontal ligament are capable of rather precise localization of the stimulus, therefore periodontal pain of all types present no difficulty in diagnosis. The offending tooth is identified by applying the pressure to it laterally or axially. It may occur as a primary periodontal inflammatory condition due to local causes such as trauma, occlusal stress, and contact with an adjacent

embedded tooth, dental treatment like dental prophylaxis, occlusal interference, over contoured or under contoured, proximal contact area. It may result from spread of pulpal infection or by direct extension from a nearby inflammatory condition involving an adjacent tooth, the maxillary antrum, or a spreading osseous infection. When periodontal pain involves several teeth, especially opposing teeth, then occlusal oversteering either by clenching or bruxism should be considered. Oversteering of posterior teeth may occur as a result of decreased vertical height of the mandibular ramus due to osseous fracture or degenerative changes in the TMJ.

- *Cracked tooth syndrome*—patient complains of pain ranging from mild to excruciating, at the initiation or release of the biting pressure. It can mimic the condition as severe as trigeminal neuralgia. A crack may involve enamel and dentin only or it may also involve the pulp and symptoms will vary accordingly. Pain occurs due to fluid movement within the dentinal tubules causing stimulation of sub-odontoblastic nerve fibers. The fluid movements are induced by pressure changes when biting with the offending cusp. If the crack involves dental pulp, direct bacterial invasion will occur with predictable pulpal inflammation and resultant pulpitis pain. Close examination of the crown of the tooth may disclose a crack in enamel, which may be better visualized by using a dye or by trans-illuminating the tooth with fiber-optic light. Crack can be confirmed by selective biting pressure using a cotton roll or a small wooden stick to allow selective localization of such pressure. It is treated by splinting of the offending cusp with a cusp protecting restoration or by removing the split cusp and then restoring the tooth.
- *Aerodontalgia*—it occurs due to effect of change in the altitude. Persons experience pain during high altitude flight or during deep sea diving. At ground level, the tooth is asymptomatic. It occurs due to subclinical pulpitis. It may occur in patients with improper obturation as improperly obturated root canal may expand during flight or during diving which creates pressure in the periapical nerve bundles and produce pain.

Musculoskeletal Pain

Pain arising from musculoskeletal structures present clinical characteristics by which they may be differentiated from other causes of deep pain; the pain relates reasonably and logically to use, movement and the demand of function. The pain can be provoked or aggravated by manipulation of the structure involved. The pain is usually but not always accompanied by some dysfunction.

Muscle pain frequently occurs in otherwise normal area, as a result of reflex protective mechanism and myofacial triggers. Muscle pain is usually felt as a non-pulsatile variable aching sensation, sometimes having a boring quality. The pain may become more lancinating and may occur spontaneously and in response to stretching, contraction, manipulation or manual palpation. Sometimes, pain is not more than a feeling of pressure whereas sometimes its intensity is increased. It may be transitory, persistent, constant, intermittent or recurrent.

Dysfunction may be expressed as tightness and weakness or impairment of muscle function such as stiffness, rigidity, swelling, and tenderness on palpation. The fact that movement and functioning modify the pain and stiffness are clinical indications of the presence of muscle pain.

- *Mechanism of muscle pain*—the mechanism is related to accumulation of metabolites after excessive use of muscles. This will result in distortion of blood vessels within the muscle, causing ischemia and hyperemia. Forceful and sustained contraction causes vasoconstriction of the relevant nutrient arteries resulting in pain.
- *Causes*—various factors like unusual yawning, biting, chewing, and strained sleeping position will cause muscle pain. Other factors which can cause muscle pain are minor blows, playing a musical instrument, period of sustained emotional tension, bruxism, excessive or prolonged opening of mouth for dental treatment, and use of local anesthetics.
- *Local muscle soreness*—it is a local condition with a local cause. It is a primary hyperalgesia with lowered pain threshold due to local factors such as strain, injury, abusive use, infection, and inflammation. When the dysfunction involves elevator masticatory muscle, trismus may result, restricting the normal mouth opening. When the muscle becomes inflamed as a result of injury or infection, the pain may relate to irritation and pressure of inflammatory exudates.
- *Muscle splinting pain*—it is defined as rigidity of the muscle occurring as a means of avoiding pain caused by movement of the part. It is a reflex protective mechanism whereby skeletal muscle becomes hypertonic and painful when contracted. It differs from muscle spasm in which contraction is sustained even when the muscle is at rest. There is pain and restriction of movement during active contraction of the involved muscle with little or no evidence of pain and restriction when purely passive movement is executed. Splinting of masticatory muscle may occur as a protective mechanism in conditions such as toothache, occlusal interference, sensitive overstressed teeth, and effect of local anesthetics, surgery, and trauma. Sustained splinting may develop into muscle spasm.

- *Nonspastic myofacial pains*—there is no muscle spasm and pain is the only complaint. Certain muscles tend to develop trigger areas within the muscles or tendons. When these sites are stimulated by ordinary function (contraction and stretching) pain impulses are generated and pain may or may not be sensed in the muscle. There is secondary referred pain which is felt in structures located at some distance from the trigger site and thus, the pain may be felt in adjacent normal structures. It may be caused by atrophied muscles due to inactivity, sustained emotional tension, illness, nutritional deficiency. Once the myofacial triggers develop within the muscle, they tend to persist as a source of intermittent and recurrent pain when the triggers are stimulated.
- *Zones of pain reference from myofacial triggers*
 - *Masseter muscle*—the masseter muscle refers to the ear, TMJ and mandibular teeth.
 - *Temporalis muscle*—the temporalis to the temple, orbit and maxillary teeth.
 - *Medial pterygoid*—the medial pterygoid to the infra-auricular and post mandibular area.
 - *Lateral pterygoid*—the lateral pterygoid to the TMJ.
 - *Sternomastoid*—the sternomastoid to the ear, pre-auricular area and widely throughout the face.
 - *Splenius capitis*—the splenius capitis to the parietal region.
 - *Trapezius*—trapezius to the neck, temple and frontal region.

Temporomandibular Joint Pain

Pain that results from TMJ and capsular ligament of TMJ is identified as masticatory pain. The pain is considerably more stable than myalgia. It can occur as intermittent arthralgia (occurs due to stress, pressure or movement) or continuous arthralgia (insidious, changes slowly, persistent and resists therapy). Central hyper-excitability tends to occur causing referred pain, secondary hyperalgesia and myospasm. The pressure bearing surfaces of the joint are non-painful due to absence of sensory receptors and nerve fibers. Pain can occur in disc when impinged upon and displaced sufficiently to stimulate receptors in the ligamentous attachment of the disc to the medial and lateral poles of the condyle.

- *Retrodiscal pad pain*—inflammation of the tissue that comprises the retrodiscal pad is called as retrodiscitis. If the condyle is displaced posteriorly because of posterior overclosure from missing teeth or from trauma, the resultant inflammatory swelling will displace the condyle anteriorly causing acute malocclusion described as contralateral premature contact of the anterior teeth with disocclusion of the posteriors ipsilaterally.

- *Capsular pain*—inflammation of the fibrous and synovial capsule is termed 'capsulitis'. Being inflammatory, pain results whenever the capsule is stretched by translatory movement of the condyle.

Vascular Pain

Pain of this type occurs because of noxious stimulation of the afferent nerve fibers that supplies sensation to blood vessels. The characteristics of vascular pain can be differentiated from other types of deep somatic and visceral pain. They are:

- *Spontaneous pain*—the pain occurs spontaneously without regard from the demand for function. Exacerbations occur spontaneously and without any provocation.
- *No pain on provocation*—provocation of the site of pain does not initiate or aggravate the pain.
- *Recurrent and periodic behavior*—the behavior of pain is typically recurrent and periodic.
- *No dysfunction*—no dysfunction accompanies the pain other than the inhibitory influence of pain and the effect of secondary muscle spasm as a central excitatory effect.

Wolf has indicated that there are several conditions that cause discomfort in vascular pain syndrome. These are dilatation of blood vessels, local edema at the painful site, edema of the vessel walls and perivascular tissues, and associated muscle pain especially in the occipital area.

The distinctive feature of vascular pain is its primary pulsatile or throbbing quality. Greater the amplitude of vascular dilatation, more pronounced the throbbing quality of the pain. This quality may be very slight at times and may be masked by muscle pain but is usually present during exacerbation. Although not invariably, there is an emotional factor that accompanies vascular pain syndrome. Frustrations, fatigue, feeling of insecurity with tension in the individual appears to set the stage for a painful episode.

Migraine

It is also called as *migraine syndrome* or *migraine headache*.

Etiology

- *Trigeminovascular neuron activation*—there is activation of trigeminovascular neurons surrounding a cephalic blood vessel due to vasoconstriction. This will lead to cerebral ischemia followed by compensatory vasodilation with subsequent pain and cerebral edema.
- *Hereditary*—it has got autosomal dominant inheritance pattern.
- *Triggering factors*—Diversity of factors is thought to be triggering the attack. It includes dietary factor (chocolate,

missing meal, aged cheese), psychogenic (stress, anxiety, depression), hormonal (menstruation, ovulation, oral contraceptive), sleep disturbance, physical (glare, flashing light, fluorescent light, odors high altitude), drugs (nitroglycerine, histamine, reserpine, hydrazine, ranitidine, estrogen) and miscellaneous (head trauma, fatigue, physical exertion).

Types

- *Migraine with aura*—in this, an aura or pre-headache period occurs. This is characterized by visual disturbances like scintillation (seeing sparks), scotoma (partial or complete loss of light perception). There is also aphasia (loss of ability to express thoughts), and numbness over one side of the face and arm.
- *Migraine without aura*—in this, no pre-headache period occurs.

Clinical Features

- *Age and sex distribution*—it begins at young age, and primarily affects women in a ratio of four to one.
- *Location*—headache is unilateral and felt in temporal, frontal, and orbital region. Rarely, it can be felt in parietal, postauricular and occipital areas.
- *Onset*—headaches often begin immediately or soon after awakening. The attack may be recurrent or episodic with variable frequency, usually 1 to 4 in a month.
- *Nature of pain*—it is started with mild headache which later increases in severity. It is of throbbing quality at the peak.
- *Associated symptoms*—there are other symptoms like nausea, vomiting, anorexia, sensitivity to light and sound, and mood changes.

Diagnosis

- *Clinical diagnosis*—pre-headache symptoms with presence of trigger zone with throbbing type of pain.

Management

- *Severe attacks*—these are controlled by ergotamine tartrate combined with caffeine, aspirin, acetaminophen, belladonna and Phenobarbital.
- *Mild cases*—treated by methergine, beta adrenergic agents and calcium channel blockers and serotonin receptor agonists.
- *Drug therapy*—drug which is used in treatment of cluster head are ergotamine (2 mg sublingual tablet), sumatriptan (50-100 mg tablet, agonist to 5-HT_{1D}) will give relief from the symptoms. Another drug which can be used are naratriptan (2.5 mg tablet), almotriptan (12.5 mg tablet), rizatriptan (5-10 mg tablet), zolmitriptan (2.5 mg tablet).

- *Non-pharmacological management*—non-pharmacological management includes diet control, stress management, sleep regulation and pressure on ipsilateral carotid artery.

Cluster Headache

It is also called as *migranous neuralgia*, *sphenopalatine neuralgia*, *histaminic cephalgia*, *periodic migraine* and *Horton syndrome*. It is an uncommon. It is the most severe headache and has been referred to as suicide headache. It is called as cluster as attacks occur in groups or cluster.

Etiology

- *Vascular cause*—this disease is caused by abnormal hypothalamic function, head trauma, and abnormal release from mast cells.
- *Triggering factors*—headache can be initiated by alcohol, cocaine, and nitroglycerine.

Clinical Features

- *Age and sex distribution*—more common in third to fourth decade of life with strong male predilection.
- *Location*—the deep intense pain may last for 15 minutes to 3 hours, which is unilateral and involves the peri-orbital area, often radiating to the ipsilateral temple and maxilla including the teeth. Pain is present in the distribution of ophthalmic nerve.
- *Nature of pain*—pain is paroxysmal, burning, and lancinating without trigger zone.
- *Alarm clock headache*—Attack develops regularly, usually once at day over prolonged periods and some patients at same time in day for this reasons, is referred to as 'alarm clock' headache.
- *Associated features*—associated symptoms, such as lacrimation from the eye, nasal congestion, rhinorrhea, forehead and facial sweating, miosis and eyelid edema, may be seen. Paresthetic sensation of skin over the lower half of the face has been also reported.

Diagnosis

- *Clinical diagnosis*—alarm clock headache without trigger zone will diagnose this condition.

Management

- *Drug therapy*—drug which is used in treatment of cluster head are ergotamine (2mg sublingual tablet), prednisone, lithium carbonate, indomethacin, methylsergide maleate, and verpamil, sumatriptan (50-100 mg tablet, agonist to 5-HT_{1D}) will give relief from the symptoms.

- *Oxygen inhalation*—inhaling oxygen may shortened attacks of symptoms.
- *Surgical*—surgical interventions have been tried. It includes trigeminal sensory rhizotomy, superficial petrosal neurectomy, gamma knife radiosurgery, and decompression of the nervus intermedius.

Temporal Arteritis

It is also called as cranial arteritis or giant cell arteritis. It most commonly affects the head and neck vessels.

Etiology

- *Inflammation and obstruction*—it is caused by inflammation and obstruction of the temporal and other cranial arteries.
- *Autoimmunity*—it may be caused by autoimmunity of elastic lamina of the artery.
- *Genetic*—there may be genetic predisposition for this disease.
- *Preceding factors*—extraction of infected tooth may cause exacerbation of pain.

Clinical Features

- *Age and sex distribution*—it occurs exclusively in individuals over the age of 50 years. It affects women more frequently than males.
- *Onset*—onset may involve one or both temporal areas.
- *Symptoms*—severe throbbing headache that often has abrupt onset and pain, usually being on one temple but occasionally involve the whole side of face. Headache may be associated with hyperesthesia. There is pain on mastication, pain in teeth, jaws and zygoma region due to involvement of internal and external maxillary artery. Patient may feel pain on chewing and talking also.
- *Nature of pain*—moderate to severe headache of deep, aching, occasional throbbing or burning quality may be present.
- *Radiating point*—pain present may radiate from the temporal region to the neck, maxilla, mandible or face.
- *Polymyalgia rheumatica*—sometimes, there is aching and stiffness of the muscle of the shoulders and hips which is often termed as ‘polymyalgia rheumatica’.
- *Tongue involvement*—pain present in tongue associated with blanching and even gangrene, which occurs because of involvement of lingual arteries.
- *Associated features*—there may be swollen and tender scalp arteries, usually the superficial temporal artery.
- *Complication*—if prompt treatment is not carried out, it may result in eye pain, photophobia, diplopia and blindness.

Diagnosis

- *Clinical diagnosis*—polymyalgia rheumatica with severe headache in temporal region.

Management

- *Corticosteroids*—corticosteroids is the treatment of choice and clinical manifestations subside within few days. Most commonly given is glucocorticoid therapy (75 gm daily). Steroids doses are reduced by 5 mg per week to maintenance dose 10 mg daily for 3 months.

Tension Headache

This is the most common type of headache with maximum number of adults suffers from it.

Etiopathogenesis

- *Psychophysiologic changes*—Psychophysiologic changes like stress, anxiety, and depression may cause this type of headache.
- *Masticatory muscle contraction abnormalities*—abnormalities of masticatory muscle contraction will also result in tension type headache.

Clinical Features

- *Age and sex distribution*—this is more commonly seen in adults and women are affected more commonly than male.
- *Nature of pain*—the pain is episodic, which is thought to be due to psychological or physical stressful events or of chronic type related to stressful daily life. It is usually slow budding pain. Pain is bilateral, dull, aching sensation, of mild to moderate intensity, with a pressing or tightening quality.
- *Physical activity*—unlike migraine, physical activity does not worsen the pain and nausea is absent.
- *Tender areas*—patients often have tender areas on the scalp and neck and palpation may reveal tender nodules in the cervical and trapezius muscle groups. These nodules may be trigger points and have the capacity to refer to the face and head area.

Diagnosis

- *Clinical diagnosis*—by looking at the symptoms, it is easy to make diagnosis of tension type headache.

Management

- *Psychological management*—simple counselling, hypnosis, relaxation and biofeedback measure are helpful.

- *Analgesic*—NSAID like aspirin are used commonly to treat tension type headache.
- *Tricyclic antidepressant*—this is also useful for tension type of headache. Most commonly given drugs are amitriptyline, and doxepin.

Chronic Paroxysmal Hemicranias

Chronic paroxysmal hemicrania is vascular type of headache which mimic migraine headache.

Clinical Features

- *Age and sex distribution*—it is more commonly seen in adulthood and more common in female.
- *Onset*—it has rapid onset characterized by unilateral head pain lasting for minute to hours.
- *Site of pain*—temporal and orbital region are site of pain. Jaw and face are also affected.
- *Associated symptoms*—there is also lacrimation, rhinorrhea, nasal stuffiness and swelling of painful area.

Diagnosis

- *Clinical diagnosis*—diagnosis is made from patient history, area of pain location and high frequency pain.

Differential Diagnosis

- *Cluster headache*—it is an attack with same characteristics of pain and associated symptoms and signs of a cluster headache, but they are shorter lasting, more frequently, occur in females, and there is absolute effectiveness of indomethacin.

Management

- *Indomethacin*—it is given in dose of 25 to 150 mg daily. It is effective in all cases of chronic paroxysmal hemicranias.

Carotidynia

A rare form of pain of vascular origin can arise from carotid artery and is therefore, known as carotidynia. It is characterized by a tender, throbbing, often swollen carotid artery on the affected side with radiation of pain to branches of the external carotid artery. The carotid tenderness is most apparent at the bifurcation or under the mandible.

Atypical Facial Pain

It refers to a mixed group of conditions which are defined and diagnosed by exclusion of other typical patterns of facial pain. It is also called as *typical facial neuralgia*, *idiopathic facial pain*, *atypical trigeminal neuralgia* and *trige-*

minal neuropathic pain. In this condition there is occurrence of strong emotional overtones of the conditions. It is usually psychogenic and occurs in patients who suffer from depressive reaction, hysteria, or schizophrenia (Fig. 18-10).

Fig. 18-10: Facial pain may be very distressing for the patient.

Clinical Features

- *Age and sex distribution*—it is more common in sixth decade with women more commonly affected.
- *Characteristic of pain*—the condition is characterized by pain that is deep, poorly localized, and vaguely described by the patient. Pain is often boring, pressing, pulling, burning, or aching. The distribution of pain is not anatomical. In general, pain is constant.
- *Referred pain*—pain is referring to temple, neck and occipital area.
- *Hot spot*—the mucosa of affected person may contain zone of increased temperature and bone marrow activity showing hot spot on technetium 99m MDP bone scan.

Diagnosis

- *Clinical diagnosis*—the diagnosis of 'atypical facial pain' can be justified where, there is an unusual character of pain, the pain does not have an anatomic distribution, the symptoms indicate some emotional illness or when significant organic development is lacking.
- *Disease to be ruled out for diagnosis of atypical facial pain*—sinus allergy, cracked tooth syndrome, headache with referred pain to face, bone impingement on nerve, Myofascial pain, neuralgias, temporomandibular joint disorders and trauma to nerve.

Management

- *Opioid analgesics*—these can be given in this patient. But their effectiveness may be diminished over period of time.
- *Tricyclic antidepressants*—tricyclic antidepressant like amitriptyline, nortriptyline is given in many cases. This

drug should be given cautiously with patient suffering from coronary heart disease.

- *Other therapy*—other therapy like psychotherapy, behavior modification, and transcutaneous electrical nerve stimulation and sympathetic nerve block are helpful in atypical facial pain.

Neurogenous Pain

Characteristics of Typical Neurogenous Pains

- *Bright quality*—the pain has a bright stimulating quality.
- *Exact location of site of pain*—the site of pain is accurately localized by the patient.
- *Analgesic blocking*—site of pain does not necessarily identify the site of origin (except traumatic neuroma). Site of pain bears a precise anatomical relationship to the site of origin, so that analgesic blocking is useful diagnostically.
- *Intense pain*—pain is extremely intense compared to the degree of stimulation.
- *No central excitatory effect*—there is no central excitatory effect like referred pain or secondary hyperalgesia.
- *Presence of trigger zones*—presence of trigger zones is the most important characteristic feature of true neuralgia.

Painful Neuritis

Neuritic pain occurs as a result of inflammatory influence on pain conduction fibers and is felt in the peripheral distribution of the affected fibers. The inflammatory process alters the relative activity of the fibers that mediate pricking and burning pain elevating the threshold of pricking pain but lowering it for burning pain. This gives the pain of a characteristic burning quality.

Sensory effects such as hyperesthesia, paraesthesia, dysesthesia, and anesthesia may be seen. If motor efferent fibers are affected, then muscular signs such as muscular tic, weakness or paralysis may be seen.

Trigeminal Neuralgia

It is also called as *Tic Douloureux* (painful jerking), *Trifacial neuralgia* or *Fothergill's disease*. The term *Tic douloureux* is only applied when the patient suffers from spasmodic contractions of the facial muscles.

Trigeminal neuralgia is an extremely painful condition as it is unique to humans. It is a syndrome in which symptoms are sufficiently distinctive to permit a reliable diagnosis solely on the basis of history. It is seriousness of these disorders that it has one of highest cause for suicide rates of any disease.

Etiology

- *Dental pathosis*—dental pathosis is believed by some investigators to be involved with the onset of trigeminal neuralgia.
- *Excessive traction*—secondary to excessive traction on the various divisions of the fifth nerve, being influenced by maxillo-mandibular relationship.
- *Allergic*—it can be secondary to an allergic and hypersensitivity reaction causing edema of the trigeminal nerve root.
- *Ischemia*—Wolf thought that ischemia at various portions of the trigeminal pathway might be responsible for the paroxysms of pain.
- *Compression distortion phenomenon*—Jannetta and others have shown subtle changes of a compression-distortion phenomenon which is usually caused by arterial loops of atherosclerotic vessels. Vessels become elongated with advancing age and with atherosclerotic involvement gain abnormal positions by wedging into the space between the pons and trigeminal nerve. It is postulated that with progressive material elongation, fascicles of adjacent nerves later suffer myelin injury and pain results.
- *Mechanical factors*—like pressure due to aneurysms of the intrapetrous portion of the internal carotid artery that may erode through the floor of the intracranial fossa to exert a pulsatile irritation on the ventral side of the trigeminal ganglion.
- *Anomalies of superior cerebellar artery*—it is the most recently blamed cause for trigeminal neuralgia. It lies in contact with the sensory root of the nerve and implicated as a cause of demyelination. Surgical elevation of artery or decompression of the sensory root has high success rate in relieving paroxysmal pain in case of idiopathic trigeminal neuralgia.
- *Secondary lesion*—conditions such as carcinoma of the maxillary antrum, nasopharyngeal carcinoma, tumors of peripheral nerve root, intracranial vascular anomalies, and multiple sclerosis may be presented with trigeminal pain.

Clinical Features

- *Age and sex distribution*—it usually occurs in middle and old age, the disease seldom occurs before 35 years of age. Incidence increases with age due to degenerative changes of the nerve fibers. It most frequently occurs in women.
- *Site*—it is more common on the right side and the lower portion of the face is more frequently affected.
- *Nature of pain*—the pain is paroxysmal, lasting only a few seconds to a few minutes and is usually of extreme

intensity. It may be described by the patient as resembling 'knife like stabs', 'lightening', 'electric shock', 'stabbing' or 'lancinating' type of pain. During the intervals between these violent experiences, there is usually no pain or a mild or dull ache. Attacks do not occur during sleep.

- **Location of pain**—the pain is confined to the trigeminal zone, nearly always unilateral and, if bilateral, is successive rather than concomitant. The mandibular and maxillary divisions are more commonly involved than the ophthalmic. In some instances, these two divisions may be simultaneously affected. The pain never crosses the midline.
- **Aggravating factors**—the pain is provoked by obvious stimuli to the face. A touch, a draft of air, any movement of the face as in talking, chewing, yawning or swallowing may evoke a lancinating attack. Later the pain may be so severe that the patient lives in constant fear of an attack. Often there is a transitory refractory period after the attack. As the attack occurs, the patient may clutch his face as if in terror of the dreaded pain.
- **Triggers zones**—'trigger zones' which precipitate an attack when touched, are common on the vermilion border of the lips, the ala of the nose, the cheeks, and around the eyes (Fig. 18-11). The patient learns to avoid touching the skin over the trigger zones which frequently makes him go unwashed or unshaven for days. Occasionally, only auriculotemporal branch may be involved. The pain and triggering is located in the auricle as well as in the temporal region.

Fig. 18-11: Common trigger zone in patient of trigeminal neuralgia. Lip, ala of nose, cheeks and eyes.

- **Neurological examination**—the neurological examination findings are normal with no objective sensory loss along the trigeminal nerve.

- **Frozen or mask like face appearance**—in extreme cases, the patient will have motionless face—the 'frozen or mask like face'.
- **Associated features**—trigeminal neuralgia may be accompanied by excess lacrimation, conjunctival injection and intense headache.
- **Effect on activities of patient**
 - **Unshaven face**—male patients avoid shaving.
 - **Avoid brushing**—as patient avoids brushing of teeth so oral hygiene is poor.
 - **Poor quality of life**—many patients will lead a poor quality of life, because of the excruciating pain.
 - **Indiscriminate dental extraction**—it is very common for these patients to undergo indiscriminate dental extractions on the effected side without any relief from the pain, because the pain of the trigger zone and pain fiber distributions often mimic pain of odontogenic origin.

Diagnosis

- **Clinical diagnosis**—abrupt onset of pain with trigger point, pain is extreme in nature with less time duration. Pain is localized to known distribution of trigeminal nerve. Spontaneous remission can occur.

Differential Diagnosis

- **Migraine**—a very common condition mistaken for trigeminal neuralgia is migraine or migranous neuralgia ((Horton's syndrome, histamine headache, histamine cephalgia), but this severe type of periodic headache is persistent, at least over a period of hours, and it has no trigger zone.
- **Sinusitis**—pain is not paroxysmal and no trigger zone present.
- **Toothache**—this can be easily identified by examining the oral cavity.
- **Multiple sclerosis**—it occurs because of autoimmune process. Specific clinical features are Charcot's triad, i.e. intention tremor, nystagmus and dysarthria or scanning speech.
- **Tumors of nasopharynx**—tumors of the nasopharynx can also produce similar type of pain, manifested in the lower jaw, tongue and side of the head with associated middle ear deafness. This complex lesion is called as trotter's syndrome. Here the patient exhibits asymmetry and defective mobility of the soft palate and affected side. As the tumor progresses, trismus of internal pterygoid muscle develops, and patient is unable to open the mouth. Here, the actual cause of pain is the involvement of mandibular nerve in the foramen ovale.
- **Post herpetic neuralgia**—neuralgia occurs after attack of herpes zoster virus. Pain is usually involved in the ophthalmic division. The history of skin lesion prior to the onset of the neuralgia usually aids in the diagnosis.

Management

Medical treatment

- *Trichloroethylene inhalation*—it has been proved to be of value.
- *Topical capsaicin cream*—topical capsaicin (nociceptive substance P suppressor) can be applied on affected area.
- *Anti-cholinergic drugs*—it was used for a short period during the late 1960s. Nowadays, this treatment modality is not used.
- *Dilantin*—diphenylhydantoin, an anti-convulsant drug has been recommended, which is effective when given orally, 300 to 400 mg per day. It may be given in single or divided doses. Side effects can include ataxia, mental confusion, nystagmus, gastrointestinal disturbance or skin rashes. Diabetic patients may have hyperglycemia secondary to the therapy and should be closely observed.
- *Carbamazepine* (tegretol) has a special effect on the paroxysmal pain. The use of this drug causes paroxysms to become separated by intervals of freedom for weeks, months or even years. These drugs decrease conductance in Na⁺ channels and inhibit ectopic discharge. This is considered to be the best conservative treatment for trigeminal neuralgia. As an initial dose, 100 mg is given twice daily until relief is established. At no time, the daily dose should exceed 1200 mg. Side effects include dizziness, unsteady gait, gastrointestinal distress, skin rashes and aplastic anemia. Nowadays, another anticonvulsant gabapentin can be given.
- *Baclofen*—recently, baclofen an antispastic drug is also being used.
- *Combination therapy*—a combination of Dilantin and Carbamazepine may also be given.
- *Clorazepam*—an anti-epileptic belonging to benzodiazepine group has been found to be useful.
- *Anti-inflammatory agents*—anti-inflammatory agents like indomethacin and short courses of steroids have been found to be useful.

Surgical treatment

- *Injection of the nerve with anesthetic solution*—local anesthetics injected near the peripheral branches of the trigeminal nerve serves to provide temporary relief from pain and helps in the diagnosis. Some patients get relief after the injection but in some cases, 6 to 7 injections may have to be given to get relief.
- *Injection of the nerve with alcohol*—the most popular material, alcohol, can be placed directly into the area where a nerve exits from the skull or more peripherally. When alcohol contacts the nerve, neurolysis occurs distal to the injection site. Nerve regeneration occurs in 6 to 24 months for most patients. But, the duration of relief from alcohol injection tends to decrease with repeated attempts probably because of the inability of alcohol to

diffuse through the fibrous tissue that resulted from previous injections. Injection of the entire 2nd division at the foramina rotundum and the 3rd division at the foramen ovale may be made in cases where peripheral injection does not give complete relief. If the injection in the ganglion is successful then the anesthesia will last from 6 months to 1 year. Generally 95% alcohol is used or procaine or monocaine 2%, chloroform 5%, absolute alcohol 70%, Ringer's solution 23% can also be used.

- *Nerve sectioning and nerve avulsion (peripheral neurectomy)*—this procedure is more lasting and effective than an injection with alcohol. Nerve sectioning is generally performed on the nerve which cannot be avulsed. The procedure can be performed on lingual, mental or buccal nerve. Peripheral neurectomy results in high degree of success in elimination of pain. But disadvantage of this technique is that result is temporary as nerve may regenerate. Peripheral neurectomies interrupt afferent impulses to the central trigeminal area and also cause damage and degeneration in the gasserian ganglion and thus inhibit nerve impulses from producing pain.
- *Electrocoagulation of gasserian ganglion*—diathermy apparatus is placed in the gasserian ganglion to coagulate and destroy it.
- *Percutaneous radiofrequency trigeminal neurolysis*—it is a technique in which there is use of controlled radio-frequency. It is performed by insertion of temperature monitoring electrode through foramen ovale into trigeminal ganglion. The temperature is raised to 60 to 90 degree Celsius. Advantages include decreased mortality and morbidity and permanent cure. Disadvantages include development of painful anesthesia, keratitis, corneal anesthesia, and sixth cranial nerve palsy.
- *Decompression and compression*—
 - *Percutaneous microcompression*—in this, inflated balloon is used to compress the gasserian ganglion.
 - *Microvascular decompression*—retromastoid craniotomy is carried out and the offending vascular structures are dissected free of the nerves at root entry zone and maintained in that position by insertion of a small piece of gelfoam or Ivalon sponge.
- *Rhizotomy*—actual cutting of trigeminal sensory root results in permanent anesthesia in most patients. The recurrence rate of trigeminal neuralgia after rhizotomy is 20%.
- *Gamma knife radiosurgery*—gamma knife radiosurgery of gasserian ganglion shows success in many patients.
- *Bulbar trigeminal tractotomy*—sensory origin of trigeminal nerve runs from the upper pons through the medulla and in upper cervical cord. This descending tract of the trigeminal nerve may be cut in the area of medulla oblongata to induce loss of pain and temperature sensation with nearly total retention of proprioception.

Glossopharyngeal Neuralgia

It is also called as '*vaguglossopharyngeal neuralgia*'. It is a variant of Tic douloureux that can mimic oral pathologic condition in which pain is confined to the distribution of the ninth cranial nerve.

Clinical Features

- *Age and sex*—this neuralgia occurs without any sex predilection in the middle aged or older persons.
- *Distribution*—the pain is generally unilateral.
- *Nature of pain*—it manifests as sharp excruciating, electric like, lancinating paroxysms of pain in the ear, pharynx, nasopharynx, tonsils or the posterior portion of the tongue. Attacks are of short duration of about 30 to 60 seconds.
- *Trigger zone*—the patient usually has a trigger zone in the posterior oro-pharynx or tonsillar fossa. An important and frequent trigger is the initiation of the act of swallowing.
- *Associated features*—it can be associated with syncope, hypotension, seizures, arrhythmia and excessive salivation can also occur.
- *Progress*—glossopharyngeal neuralgia has a tendency towards remissions and exacerbations. Pain free intervals of seconds, minutes, hours, days, and years are common.

Diagnosis

- *Clinical diagnosis*—pain like trigeminal neuralgia with trigger zone present in tonsil and pharynx area.

Management

- *Topical anesthetics*—patient may get pain relief after applying topical anesthetics to tonsil and side of pharynx on side of pain.
- *Other therapy*—other therapy like carbamazepine, oxcarbazepine, baclofen, phenytoin, lamotrigine and resection of glossopharyngeal nerve can also be initiated.

Geniculate Neuralgia

It involves the intermediate nerve of Wrisberg, an important component of the facial (VII) nerve.

Causes

- *Neuroma and vascular malformation*—pathological involvement of the sensory intermediate nerve root of the VIIth cranial nerve due to neuroma; vascular malformations, etc. are the causes.
- *Zoster infection*—zoster infection of geniculate ganglion canal also cause this type of neuralgia. This is also called as Ramsay Hunt syndrome.

Clinical Features

- *Age and sex*—females are affected more commonly than males. It occurs more commonly in old aged persons.
- *Location of pain*—ear, anterior tongue, soft palate.
- *Nature of pain*—the pain may be felt in the ear with occasional pain in the palate and the tongue.
- *Trigger zone*—triggering is caused by touching the ear.
- *Vesicle*—this can be seen in ear of the patient in case if it is associated with zoster infection.

Diagnosis

- *Clinical diagnosis*—pain in ear, tongue, and soft palate with vesicle formation may give clue to the diagnosis.

Management

- *Topical anesthesia*—topical anesthesia of the external auditory canal may arrest pain in some cases.
- *Steroid*—short course of high dose steroids therapy is useful.
- *Acyclovir*—this is helpful in case of geniculate neuralgia associated with zoster infection.
- *Other drugs*—other drugs like oxcarbazepine, carbamazepine and gabapentin are also useful.
- *Surgery*—if all the above treatment fails then excision of nervus intermedius and geniculate ganglion should be carried out. Microvascular decompression can also be done.

Occipital Neuralgia

Occipital neuralgia occurs due to trauma, neoplasm, and infection of greater or lesser occipital nerve. It is presented as paroxysmal stabbing pain in the occipital region. There is tenderness at superior nuchal line. It is managed by occipital nerve block, corticosteroid and neurolysis.

Post-herpetic Neuralgia

It is discussed in Chapter 31: Viral Infections.

Symptomatic Neuralgia

Neuralgic pain resulting from pathologic lesions is called as symptomatic neuralgia.

Characteristics

- *Atypical manifestations*—such as prolonged or nearly continuous paroxysms of pain.
- *Bridging of paroxysm*—definite bridging of paroxysms with a more continuous aching or burning pain.
- *Bilateral pain*—bilateral neuralgic pain.
- *More nerve involvement*—neuralgic involvement of two or more cranial nerves simultaneously.

- *Sensory manifestation*—neuralgia along with other sensory manifestations such as hypoesthesia, paresthesia, dysesthesia, anesthesia.
- *Motor manifestation*—neuralgia along with muscular weakness or paralysis or other autonomic signs.
- *Failure to respond to therapy*—failure to respond to reasonable therapy.

Eagle's Syndrome (Elongated Styloid Process) or DISH Syndrome

Nowadays, this syndrome is called as *DISH syndrome* (diffuse interosseous skeletal hypertrophy). It is also called as Stylohyoid syndrome, Carotid artery syndrome. Styloid process is originated from temporal bone. It is connected to hyoid bone by stylohyoid ligament. Elongation of the styloid process leads to impingement or compression of adjacent nerves leading to Eagle's syndrome.

Types

- *Classic type*—the classic type occurring after tonsillectomy resulting from surgical exposure of the styloid process. Scar formation will result in pressure on nerve causing the pain while swallowing.
- *Carotid artery syndrome*—the carotid artery syndrome resulting from calcifications of the stylohyoid ligament and elongated styloid process which encroaches the external or internal carotid vessels produce vascular pain.
- *Traumatic Eagle's syndrome*—it develops after fracture of mineralized stylohyoid ligament.

Clinical Features

- *Age*—it is more commonly seen in adults.
- *Sign*—sometime, elongated styloid process can be visualized in pharyngeal area.
- *Symptoms*—pain in the lateral pharyngeal wall and side of the lower face and neck. It may mimic glossopharyngeal neuralgia.
- *Associated symptoms*—associated symptoms include difficulty in swallowing, sore throat, glossodynia, and headache and dull to severe hemifacial pain. Blurred vision and vertigo have also been seen.
- *Characteristic sign*—patients with Eagle's syndrome will characteristically rotate their head slowly to avoid provoking pain. The pain can be demonstrated when pressing the pharyngeal wall against the styloid process and when swallowing or opening the mouth wide.

Radiological Features

- Elongation can be seen radiographically. It is more commonly seen panoramic radiograph. Mineralization is also noticed on the radiograph (Fig. 18-12).

Fig. 18-12: Elongated styloid process seen on radiograph.

Diagnosis

- *Clinical diagnosis*—pain in lateral pharyngeal wall, blurred vision will aid in diagnosis.
- *Radiological diagnosis*—elongated styloid process can be seen radiologically.

Management

- *Topical anesthesia*—application of topical anesthesia will not relieve pain but infiltration of a local anesthetic around the styloid process will provide relief.
- *Surgical*—it is treated by surgical segmentation or resection of the elongated styloid process.
- *Corticosteroid injection*—local injection of corticosteroid sometimes provides relief.

Other Causes of Symptomatic Neuralgia (Fig. 18-13)

- *Trotter's syndrome*—patient complains of neuralgic pain in the mandible, side of head, tongue, and ear. It is associated with middle ear deafness and defective mobility of the soft palate. Trismus of jaw sets in as a result of involvement of internal pterygoid muscle. The cause is tumor of the nasopharynx, starting in the pharyngeal wall involving the eustachian tube.
- *Pterygopalatine fossa syndrome*—this consists of maxillary dental pain, infraorbital and palatal anesthesia, blindness and pterygoid muscle paralysis. The cause is a metastatic tumor to the pterygopalatine fossa.
- *Jacob's syndrome*—this consists of most of the feature of Trotter's syndrome and the Pterygopalatine fossa syndrome plus ophthalmoplegia. The tumor is an intracranial lesion in the middle cranial fossa.

Fig. 18-13: Causes of symptomatic neuralgia.

- *Godtfredsen's syndrome*—it consists of ophthalmoplegia and trigeminal neuralgia usually associated with paralysis of the tongue. The tumor is located in the nasopharynx extending intracranially.
- *Foix's syndrome*—this consists of ophthalmoplegia and maxillary trigeminal neuralgia. This is due to tumor, aneurysm or thrombosis involving the cavernous and/or the lateral sinus.
- *Raeder's syndrome*—it is also called as paratrigeminal syndrome. It is most common in males chiefly those of the middle age and usually appear suddenly. Unilateral severe headache with ocular symptoms like increased lacrimation or greater viscosity of lacrimal fluid, and ipsilateral motor and sensory trigeminal dysfunction. It is due to tumor of middle cranial fossa or of the gasserian ganglion.
- *Post-traumatic neuralgia*—this presents the features which identify it as neurogenous. It combines the characteristics of both painful neuritis and neuralgia. The syndrome has persistent, unremitting though variable, bright, burning pain that suggests painful neuritis and may be accompanied by other sensory, motor and/or autonomic effects that characterize neuritic manifestations.

- *Carotid body tumor*—swallowing dysfunction associated with vocal cord paralysis and patient may complain of glossopharyngeal pain.
- *Costen's syndrome*—it is characterized by impaired hearing, dizziness, and burning sensation in the throat and tongue. Headache about the vertex, occipital region and behind the ears, stuffy sensation in the ears, especially at mealtime, and otalgia.
- *Multiple sclerosis*—it is a disease featuring progressive demyelination of nervous tissue with episodes of relapse and remission. It is slightly more common in females and the usual age of onset is between 20 to 40 years of age. There are a wide range of symptoms reported by the patients with the commonest being : optic neuritis, which is associated with loss of visual acuity and colored vision, and sometimes pain in the eye, weakness of one or both lower limbs, impairment of cutaneous sensations in the lower limbs and trunk, vertigo and ataxia. Bilateral trigeminal neuralgia has been found to occur more in patients with multiple sclerosis than in patients with idiopathic neuralgia.
- *Cerebellopontine angle tumor*—it rarely causes trigeminal neuralgia and pain in the trigeminal area. The majority of these tumors develop within the temporal bone along the course of the vestibular division of the auditory nerve, from where they spread to occupy space between the brain and cranium. The most common symptoms are deafness, headache, tinnitus and loss of balance. Pain, if any, is usually of low intensity, steady, dull ache; hypoesthesia is considerably more common.

Psychogenic Pain

Pain that originates in the mind refers to this pain disorder, for which, there is no apparent physiologic or organic basis and in addition, the patient has a definite history of psychological problems or it implies the presence of emotional or personality disorder.

Psychogenic Intensification Pain

Most psychogenic pains of the mouth and face are of this type. It is usually chronic, lack of adequate peripheral cause, non-anatomical location of the complaint and deviated pattern of behavior raises suspicion about presence of this type of pain syndrome.

Frustration, anxiety, uncertainty, apprehension, fear and tension from the ingredients of pain intensification through the reduced central inhibitory influence on the setting of the synaptic gate in the brainstem.

All conditions, both central and peripheral, that open the gate to the passage of impulses are felt as painful episodes and cause pain that is not due to noxious stimulation; so much is the lack of inhibitory control over the neural impulses that even occurs in the unconscious

state. As a result, teeth may become unduly sensitive or actually painful. They may hurt when touched, moved, pressed, or stressed through occlusal use, or subjected to stimulants such as tooth brushing, flossing, thermal changes or ingestion of sweet. In such situations, many or all of the teeth may become painful. Tension and anxiety may lead to spasm of striated and smooth muscles, inducing local conditions that can become painful.

Conversion Hysteria Pain

Psychic energy from a repressed idea or complex is converted into nervous stimuli giving rise to physical symptoms. Psychological trauma sustained by the patient may become expressed as physical illness. It has been described as 'psychogenic regional pain syndrome'. It is hallucinatory and remotely localized in a way that is psychologically related to the noxious situation.

Delusional Pain

It is created in the subject's mind as a hallucination and is symptomatic of serious psychiatric problems. Delusional pains of the mouth and face is a manifestation of schizophrenic hallucination which is very rare.

Burning Mouth Syndrome

Burning mouth syndrome is common dysesthesia (sense distortion) described by patient as burning sensation of oral mucosa in absence of apparent mucosal alteration.

Etiology

Local factors

- *Contact allergy*—substances in denture material can be allergic like monomer methyl methacrylate, epoxy resin and glycol.
- *Chronic mechanical trauma*—chronic mechanical trauma may occur due to denture, clasp etc.
- *Habits*—oral habits like clenching, grinding, and chronic tongue thrust habit may be causative factors.
- *Infection*—infection with *Candida albicans*, fusospirochetal infection.
- *Xerostomia*—xerostomia due to irradiation, immunological deficiency, systemic causes, medication focal disease.
- *Other*—other factors like TMJ dysfunction, geographic tongue, oral submucous fibrosis, esophageal reflux, angioedema, trauma to lingual nerve, and acoustic nerve neuroma may cause burning mouth syndrome.

Systemic Factors

- *Nutritional deficiency*—vitamin deficiency like pernicious anemia, other B complex vitamins, folic acid, iron

deficiency anemia may be causative factors for burning mouth syndrome.

- *Diabetes mellitus*—this may be one of important causative factors for burning mouth syndrome.
- *Psychological disorders*—depression, anxiety, psychosocial stress.
- *Gastrointestinal problems*—chronic gastritis, chronic gastric hypoacidity may cause burning mouth syndrome.
- *Endocrine disorders*—hypothyroidism and estrogen deficiency.
- *Others*—menopause, diabetes, medication, AIDS, Parkinson's disease, mercurialism can be causative factors.

Clinical Features

- *Age and sex distribution*—it occurs in 5.1% of the general population and patients older than 50 years of age. Females are affected more as compare to males.
- *Site*—tongue is most frequently affected followed by denture bearing areas, buccal mucosa, throat and floor of the mouth.
- *Nature of pain*—pain is present in the morning and it can persist and become aggravated during the day with maximum intensity being in the evening. Half of the patients have continuous pain which may be mild, moderate or severe. Some patients exhibit waxing and waning pattern that occurs several days and week.
- *Associated features*—headache, insomnia, lethargy, decreased libido, mood changes (irritability, depression, and decreased desire to socialize).
- *Aggravative and relieving factors*—aggravative factors include tension, fatigue, and hot foods. Sleeping, eating and distraction reduce intensity.
- *Scaled mouth syndrome*—this is the term used for patient who suffers from burning due to angiotensin converting enzyme (ACE).

Diagnosis

- *Clinical diagnosis*—waxing and waning pattern presented for many days. Pain is mild with increasing intensity throughout the day.

Management

- *Removal of cause*—any cause which is causing the burning mouth syndrome should be removed. For example denture adaptation, allergy control, habit control, consulting.
- *Nutritional supplement*—nutritional supplement like ferrous sulfate 300 mg TDS, iron sulfate 2.5 ml/day IM, cyanocobalamin 250 mg/day, pyridoxine HCl 25 to 100 mg/day, riboflavin 10 mg/day, thiamin HCl 5 to 30 mg/day, folic acid 0.1 to 34 mg/day should be given.

- *Mood altering drugs*—mood altering drug like chlordiazepoxide shows improvement in patients.
- *Other drugs*—other drugs like amitriptyline, clonazepam, alpha lipoic acid, hydrocortisone locally, nystatin oral suspension, ketoconazole, and diphenylhydramine HCl for rinsing.

Therapeutic Modalities of Pain Control

Analgesics

- *Non-narcotic analgesics*—it includes aspirin, acetaminophen and NSAIDs. This drug inhibits generation of pain by blockage of prostaglandin synthesis, especially prostaglandin-E which, via cyclo-oxygenase pathway, forms from arachidonic acid that occurs as part of the inflammatory process by initiating action on the enzyme cytokinase. Prostaglandin is also useful to maintain protective layer of gastric mucosa. That is the reason, after administration of NSAID patient suffers from gastric irritation and gastrointestinal bleeding.
- *Mild pain*—oral administration of 650 mg of aspirin or 200 mg Ibuprofen every four hours is indicated for mild pain. Aspirin has got numerous side effects like ulceration, epigastric distress, nausea, vomiting and increased bleeding time. Aspirin binds irreversibly to platelet cyclo-oxygenase pathway. This prevents platelet production of prostaglandin and thromboxane, substances that are essential for platelet aggregation, thus increasing the bleeding time. For patients, for whom the use of aspirin-like drugs is contraindicated, oral administration of 600 to 1000 mg acetaminophen can be used. Other drugs used are diflunisal, naproxen, and fenoprofen.
- *Moderate pain*—in cases of moderate pain, 400 to 600 mg of ibuprofen can be used. If there is failure to obtain adequate relief, addition of 60 to 90 mg of codeine will increase the opioid effect. In aspirin intolerant patients, 600 to 1000 mg acetaminophen combined with 60 mg codeine or 5 mg oxycodone is generally used.
- *Severe pain*—the onset of severe pain can be suppressed by the use of long acting local anesthetics such as bupivacaine or etidocaine in combination with NSAIDs.
- *Narcotic analgesics*—it contains morphine like agonist, partial agonist and mixed agonist antagonist. These drugs act on CNS receptors to induce peripheral analgesic effect and they depress nociceptive neurons while stimulating non-nociceptive neurons. It is used in managing severe acute pain.
- *Agonist antagonist drugs*—for example: buprenorphine, butorphanol and pentazocine are used to treat moderate to severe pain.

Adjuvant Drugs

Several pharmacological agents are useful for palliative and cause-related therapy.

- *Analgesic balms*—it gives soothing palliative relief from inflammatory pain of both superficial and deep somatic category when applied topically on exposed or ulcerated area. Aloe Vera juice is an ancient variety used for superficially generated pain. Balsam of Peru and eugenol are well known balms. They are applied in various forms like ointment, liquid, and adhesive dressings.
- *Anticonvulsants*—phenytoin has capability of suppressing pain of paroxysmal neuralgia in about 20% of cases. Carbamazepine which can be used in trigeminal neuralgia is effective in 70% of cases.
- *Antidepressants*—some patients with vascular pain and chronic pain may respond to antidepressant medication. Some antidepressants like tricyclic and MAO (monoamine oxidase) inhibitors are helpful in managing chronic pain syndromes.
- *Antihistaminic*—antihistaminic counteract the vasodilator effect of histamine by blocking certain histamine receptors. They may be useful in allergic conditions and some vascular pain syndromes. A direct analgesic effect is reported by use of several antihistaminics like diphenylhydramine.
- *Antimicrobials and antiviral agents*—antinociceptive benefits of such agents related to resolution of infection that cause pain.
- *Dietary supplements*—the chief relationship between diet and pain appear to be with L-tryptophan which converts into serotonin. Brain and spinal cord serotonin neuron are actively involved in nociceptive response. The synthesis of brain serotonin is dependent on deposition of plasma tryptophan, 90% of which is bound to albumin and must compete with other amino acids at blood-brain barrier. The use of tryptophan and other amino acids as dietary supplement appear to be a valid approach to otherwise refractory chronic pain problems. Adequate dose of 4 mg / day with low protein, low fat, high carbohydrate diet should be given.
- *Neurolytic agents*—the most commonly used is 95% ethyl alcohol, although effective, neurolysis does not produce regeneration of peripheral axons and gives only temporary relief. The hazards include extensive local fibrosis and deafferentation effect restrains its use.
- *Nor-epinephrine blockers*—in analgesic, blocking of the stellate ganglion for the control of causative pain about orofacial region norepinephrine blockers are used.

- *Tranquilizers*—the major tranquilizers like phenothiazine are very useful in pain control by reducing modulatory effect, anxiety and apprehension.
- *Muscle relaxant*—medication that tends to relax skeletal muscle has some value in the treatment of myogenous pain especially. They are helpful in obtaining occlusal disengagement.

Cause Related Therapy

Many who experience orofacial pain have organic structural cause for it. You have to identify the cause and eliminate it. Therapy is given accordingly.

Relaxation

To an extent, tension and stresses are etiological factors in pain. Following techniques are used to provide relaxations.

- *Autosedation*—it has been demonstrated that some functions are automatic and beyond the voluntary influence. However, it can be manipulated by conscious mental procedure. There are a number of relaxation techniques that involve mental discipline and self-training like yoga. Modulating effects of conscious mental autosuggestion is very reactive and should be actively utilized in pain management. Sometimes music may be helpful in relaxation techniques.
- *Biofeedback*—EMG feedback has been found to be useful in reducing hyperactivity of masticatory muscles in individuals who are prone to clench their teeth during day time. EMG biofeedback apertures include pair of surface electrodes made up of silicon rubber, voltmeter with amplifier and visual and auditory display. In training muscle relaxation, the electric potential of masticatory muscles can be recorded and displayed on digital voltmeter so that patients can observe the amount of tension and try to relax. EMG feedback training aims at teaching the patient to become aware of the tension in the masticatory muscle and to learn to relax it.
- *Occlusal disengagement*—occlusal disengagement induces substantial beneficial effects on discomfort of TMJ disorders. Disengagement sets occlusion at rest and causes the masticatory system to relax. Occlusal disengagement can be accomplished by
 - *Voluntarily disengagement*—patient is asked to voluntarily leave its teeth apart.
 - *Chewing gum*—variety of simple habit training as by placing thin parts of chewing gum between molar teeth.
 - *Muscle relaxant*—we can also use muscle relaxant for the occlusal disengagement.
- *Interocclusal device*—interocclusal device significantly decreases nocturnal EMG activity or bruxism. They tend to normalize the sensory and proprioceptive impulses generated by occlusal dysfunction and thus shut off afferent input that initiate muscle splinting and aggravate myoplastic activity. Device uses are disengaging splint, occlusal correcting splint and mandibular re-positioning splint.

Counseling

Armed with good understanding of nature of pain and how it is modulated, the doctor can use counseling as a powerful tool in the management of pain.

- *Emotional stress*—due to anxiety and fear, a person in pain may be emotionally upset which accentuates his suffering. An accurate explanation of pain should be given to the patient in a language that can be understood by him. It will boost the patient's confidence and hope. Honest words of assurance can allay fear and diminish anxiety thus reducing the level of suffering.
- *Evaluation of consequence*—apprehension concerning the consequent damage and expecting future threat to one's well-being cause psychological intensification of painful experience. This can be reversed by open discussion on realistic consequences that exist.
- *Inhibitory influence*—the excitatory influence of attention directed towards the complaint can be countered with distraction by directing the mind towards thinking that is more positive.
- *Coping strategies*—attention and tender loving care should reward illness behavior. Severe pain may be made tolerable by replacing the suffering with something better to do like doing something that benefits others, activities that direct attention away from self or constitute occupational therapy.
- *Hypnotherapy*—anti-nociceptive methods can be used, provided that the pain is not due to psychoneurosis. Some suffering is too valuable to the patient to be given up. Personality, disintegration may follow withdrawal of pain. Effects depend on susceptibility of the patient to suggestion. Hypnosis is effective in large number of patient's presenting symptoms of severe pain of organic origin.
- *Psychotherapy*—it is needful in mainly chronic pain syndromes like conversion hysteria and delusional pain. Pain behavior may be unlearned by manipulation of consequences such as withdrawing positive reinforcement and rewarding better behavior. It requires full knowledge and cooperation not only of the patient but also of those in close personal contact which includes family members, doctors, nurses and the therapist.

Physiotherapy

- **Massage**—it is primarily used to improve biomechanical functioning. It is indicated for use in pain management. Deep massage especially of muscles is an important therapeutic measure in pain management.
- **Exercise**—an immobilized muscle not only loses its strength by disuse atrophy but also shortens due to myofascial contraction. Exercise increases the pain threshold. Forceful contraction of antagonist muscles causes reflex relaxation of agonist muscles. This principle is used in masticatory myospasm. For example, spastic elevator muscle is relaxed by opening mouth against resistance; retrusion of protruded mandible against resistance leads to relaxation of spastic lateral pterygoid muscles. Stimulation of muscle proprioceptors to normalize the excessive EMG activity in painful spastic skeletal muscles can be helpful.
- **Deep heat therapy**—physiotherapy in the form of penetrating heat has its value in treating the patient.

Diathermy is used for treating inflammatory type of pain.

- **Trigger point therapy**—following method is carried out in trigger point therapy.
 - **Spray and stretch method**—in this, technique vapocoolant (fluorocarbon), spring capped bottle with calibrated nozzle that delivers fine stream is needed. The muscle should be moderately stretched just short of pain. The vapocoolant is applied by using parallel sweeps in one direction traveling towards the reference area. The nozzle is held 15 to 18 inches away from the skin and stream is directed at an acute angle of 30 degrees. After 2 to 3 sweeps muscle should be rewarmed. At the end, moist heat is applied and range of motion exercise instituted.
 - **Ischemic compression**—in this, 20 to 30 lbs of pressure at trigger site for 1 minute is applied while the muscle is stretched just short of pain.
 - **Ultrasound therapy**—frequency used is about 27 MH lasting for 10 to 15 minutes. Analgesic effects or short wave diathermy is supposed to be caused partly by mechanical vibration and partly by deeply penetrating thermal energy. The increase in temperature of deep tissues may become considerable (41 to 45 degree) and result in increased elasticity and plasticity of tissue collagen.
- **Physical activity**—in patients with chronic pain, maintenance of the physical activity is important. Extending the exercise to the limit of pain tolerance is significantly beneficial. The more the exercise is performed the fewer is the pain behavior display.

Fig. 18-14: Management of orofacial pain diagrammatic representation.

Sensory Stimulation

- **Cutaneous stimulation**—in this, effects occur through stimulation of thick myelinated cutaneous afferents like beta neuron chiefly. It is done by pressing and rubbing the skin over the site of injury. Superficial massage is also important in reducing pain. It is enhanced by adding stimulating substances like alcohol or menthol ointment. Other methods which used for cutaneous stimulation are use of mustard plaster and circulatory bath water. Mustard plaster is an age-old pain remedy. It is well known that mild stimulation of nociceptor also increases the pain inhibitory mechanism. Circulatory bath water has a therapeutic effect and a brisk stream of shower water directed against neck and back gives relief.
- **Transcutaneous electrical nerve stimulation**—Nowadays, it has become a popular form of pain control. The unit employs low intensity tardic current at a high frequency of 50 to 100 Hz, applied to skin through electrodes attached by a conduction paste. It is used to stimulate nonnociceptive cutaneous afferent neurons that activate descending pain inhibition mechanism without

involving opioid peptides. Analgesic effect ranges from 50 to 70%.

- *Electro-acupuncture*—it utilizes low frequency 2 Hz but high intensity current. It is applied at a specific point called as acupoint. It is used to stimulate muscle nociceptors which in turn activates the endogenous anti-nociceptive effect. The anti-nociceptive effect is not immediate but requires induction period of 15 to 20 minutes. Analgesia may be segmental or general. The segmental relief of pain is thought to involve cerebrospinal fluid enkephalin level while general effects appear to involve the action of beta endomorphin secreted by pituitary gland in the bloodstream.
- *Percutaneous stimulation*—it is done by electrode that penetrates the skin. Subcutaneous nerve stimulation by an electric current produces prolonged anesthesia that is not reversed by naloxone, which indicates that it does not recruit the opioid peptide. New term is percutaneous stimulation of the periosteum by insulated needle. It uses 9 to 12 volts at 100 to 300 Hz for 45 minutes.

Local Anesthesia

- *Analgesic blocking*—to arrest the pain of myospasm by analgesic blocking has marked therapeutic effect. It is preferable to block nociceptive pathway than muscle proper.
- *Interruption of pain cycle*—on the basis of clinical evidence, a cycling mechanism appears to be implicated in several pain syndromes that occur in the orofacial region. Such cycling is effectively interrupted by local anesthetic blockage of nociceptive impulses at the primary source or somewhat along its mediating pain pathway. Remission of pain outlasts the period of anesthesia.
- *Trigger point therapy*—injection of short acting local anesthetics of low myotoxicity at myofascial trigger point located in muscle tissue effectively resolves the referred pain syndrome. This therapy is required when triggered point are located in the muscle tendon.
- *Sympathetic blockage*—the diagnostic analgesic blocking of afferent sympathetic pathway to identify mediation by such neuron. Stellate ganglion analgesic block is as effective as amitidine for treatment of reflex sympathetic dystrophy. Other syndromes in which it is effective are herpes zoster and post-herpetic neuralgia.

Infections of Oral Cavity

Introduction

Facial infections are relatively a common presentation to both, general medical and dental practice. Most originate in superficial structures (skin, subcutaneous tissue, etc.) and are often easily diagnosed and treated.

Infections originating in deeper structures can be severe, rapidly progressive and may cause prolonged morbidity, long-term complications as well as potentially endanger life. Efficient treatment requires accurate diagnosis, early aggressive medical treatment and in most cases, urgent decisive surgical management.

Infection is a clinicopathological entity involving invasion of the body by pathogenic microorganisms and reaction of the tissues to microorganisms and their toxins. Soft tissue infections of head and neck are commonly encountered in routine practice in dentistry. These infections may be odontogenic or non-odontogenic in origin. Once the infection extends past the apex of the tooth the pathophysiology of the infectious process can vary, depending upon the number and virulence of the microorganisms, the host resistance and anatomic geography.

These odontogenic infections can become severe, life threatening facial space infections. These infections have the potential to spread through facial planes of head and neck thereby compromise the vital structures in these regions, e.g. intracranial odontogenic infection leading to necrotizing fascitis of head and neck. Most odontogenic infections can be managed successfully with minimal complications. The key to successful management is sound surgical principles.

Host Defense Mechanism

The relationship between the host and microbes is a dynamic one. Usually, host resistance is the dominant factor. On the other hand, when the host resistance is

lowered, microbes predominate and clinical infection occurs. In establishing the presence of infection there is interaction between three viz. factors host, environment and microbes.

A compromised patient is more likely to have infection and this infection can rapidly acquire a serious form. Hence the patient's history is one of the important criteria to recognize the patient ability to defend himself against the infection. The adverse relationship between the host and the infectious microorganism can be best understood by imagining a balance on which the pathologic attribute of microbes are weighed against the protective mechanisms of the host.

Body defends against the microbial invasion by three major defenses—local defense, cellular defense and humoral defense. The microorganisms on the other hand use two weapons in this battle, i.e. virulence and number of microbes.

Local Defense

- *Epithelial lining*—it is the first line of defense. It physically hinders the penetration of surface bacteria into deeper tissues. When there is a break in the continuity of the anatomic barriers, the microbes find an easy way into deeper tissues. In the oral cavity, the bacterias find way through deep periodontal pockets and necrotic dental pulp.
- *Secretory and drainage system*—this system assists host defense by physical and chemical action. The mucociliary activity, peristaltic motion and flushing action, that all result in drainage and mechanical removal of bacteria. Obstruction and impairment of drainage almost always result in infection. Secretion of the oral cavity, i.e. saliva and swallowing mechanism helps to remove the food particles and also prevents stagnation of microbial flora at one site. Chemical constitution of saliva changes as the pH changes. This favors the growth

of bacteria. Hence, the pH of saliva should be maintained to control the bacterial growth.

- *Microbial floral interference*—this refers to inhibitory effect exerted by one microorganism on the growth and population of other. The normal flora of oral cavity is able to discourage the growth of new species of bacteria.
- *Mucosal immune system*—beneath the mucosal epithelium, lamina propria and connective tissue contain a large number of immunocompetent cells. The B lymphocytes and plasma cells with the help of certain T lymphocytes locally synthesize IgA, some IgE and small amounts of IgG and IgM. The immunoglobulin in secretion together with the local protective factor constitutes mucosal immune system. IgA inhibit the colonization of mucosal epithelial cells by occupying potential sites of attachment. They also neutralize the toxins and viruses.

Humoral Factor

- *Immunoglobulin*—the host synthesizes specific protein molecules, with antibody activity, in response to antigenic stimulation. These proteins are derived from B lymphocytes and plasma cells and are called as IgA, IgM, IgD, IgG and IgE. Secretory IgA and IgE antibodies directly prevent the attachment of pathogenic bacteria or parasites to epithelial receptor cells, which is very crucial in preventing colonization and subsequent infection. By direct action, antibodies can neutralize viruses and microbial toxins.
- *Complement system*—this consists of group of serum proteins, which by a series of reactions produce and release byproducts whose functions are to initiate inflammatory reaction, regulate and enhance phagocyte function and attack the bacterial cell membrane. The activation of complement system by either pathway results in generation of cytolytic activity, chemotactic factor and mediator, anaphylactic toxin, opsonising and phagocyte enhancing activity, and immune adhered activity.

Cellular Component

- *Polymorphonuclear leukocytes*—PMNs are the first phagocytes to respond to the chemotactic factor elaborated by complement system. Thus, they predominate in acute infection, which persists for about one week. Their function is to clear up the battle field.
- *Lymphocyte*—it consists of two types of cells—B lymphocyte and T lymphocyte. Both T cells and B cells produce lymphokinin hormone that plays several vital roles in resistance to infection. Primarily they regulate the action of phagocytic cells. Thus lymphocytes are responsible for modulation and control of phagocytic cells.

- *B lymphocytes*—they are responsible primarily for combating extracellular pathogens, particularly those bacteria that are not able to survive inside phagocyte or other cells which secrete specific antibodies against which, the host has previously been exposed.
- *T lymphocyte*—T cells, on the other hand, are responsible for combating intracellular pathogens which are primarily viruses and those bacteria that can survive within phagocyte cell. In addition, T cells are responsible for surveillance against the proliferation of tumor cells. These complex functions of T cells are described in general as cell mediated immunity.
- *Macrophage inhibiting factor*—it inhibits the random movement of macrophages away from the site of infection, keeping them where they are needed.
- *Interferon*—it enhances lysis of bacteria by phagocytes.
- *Mitogenic factor*—secreted by T cells; stimulates B cell proliferation in the body. This will result in antibody response to antigenic stimulation.

Microbial Factors

Pathogenicity

- *Definition*—pathogenicity is the ability of a microbial species to produce disease.
- *Mechanism*—it involves subversion of host cell metabolism, and production of host cell lytic factor.
- *Toxin*—production of potent toxins which systemically act on the host. To set up an infectious process, a microorganism must be able to do the following:
 - To enter the host
 - To multiply in host tissues
 - To resist host defense
 - To damage the host.

Virulence

- *Definition*—it is the term applied to the properties in particular strain microorganisms. Virulence is the sum total of several determinants such as adhesion, toxigenicity and communicability.
- *Exaltation and attenuation*—enhancement of virulence is known as *exaltation* and reduction of virulence is known as *attenuation*.
- *Adhesion*—the initial event is the attachment of bacteria to the body surface. This attachment is not a chance event, but it is a specific reaction between the surface receptors on the epithelial cells and the adhesive structures on the surface of the bacteria.
- *Invasiveness*—this refers to the ability of a pathogen to be spread in the host tissue after establishing infection. Highly invasive pathogens cause generalized infections and less invasive one causes localized infections.

- **Toxigenicity**—bacteria produce two types of toxins, i.e. exotoxin and endotoxins. Exotoxins are heat labile proteins excreted by certain bacteria and they diffuse readily into the surrounding tissues. Endotoxins are heat stable polysaccharide protein lipid complexes, which form an integral part of the cell wall of gram negative bacteria.

Effect of Infection on Host

- **Inflammatory reaction**—infectious agents initiate, in the host, a series of reactions that are collectively called as 'inflammatory reaction'.
- **Protective reaction**—this response results in generation and release of mediators, microvascular changes and mobilization and activation of leukocytes, all designed to eliminate the infectious pathogens and repair tissue injury. Therefore, these reactions are protective in nature.
- **Direct injury to host cells**—direct injury to the host cells, enhancement of the parasite's invasiveness and amplification of these effects occur due to neutralization of host defence.
- **Symptoms**—there is fever, endotoxic shock and intra-vascular coagulation.
- **Hypersensitivity reaction**—the pathogen or its products, in certain situations, may combine with antibodies or sensitized mononuclear leukocytes to produce harmful immunologic effects called as 'hypersensitivity reaction'.
- **Compromised host**—person whose defense mechanisms have been lowered as a result of diabetes, tuberculosis, rheumatic fever, malignancy, radiation therapy, use of therapeutic immunosuppressive drug or antibiotics, extensive skin burns, genetic deficiency of immune system and malnutrition.

Oral Microflora

The microbial flora that is characteristic of a particular site in majority of the population is referred as the indigenous flora or normal flora. The oral microflora at birth is aerobic and after eruption of teeth, anaerobes are also established. The intrinsic source of microorganisms in the oral cavity is gingival crevice material, pus cells and epithelial cells undergoing degradation and salivary component.

Anatomic Considerations in Dentoalveolar Infection

- **Maxillary central incisor and lateral incisor**—the apices of the roots of central and lateral incisors lie closer to the labial alveolar process. The infection from these therefore exits through the bone in this region. The further spread is influenced by orbicularis oris and the subcutaneous tissues at the base of nose, which tend to limit the infection at the base of the nose.
- **Maxillary canine**—the position of the roots of the canine is in the labial aspect. So, the infection will exit from the bone on the labial aspect. The relation of the levator anguli oris muscle then determines whether the infection will be localized in the oral vestibule or will progress extra-orally. If the site of perforation is below the attachment of the levator anguli oris, then vestibular swelling will occur. If the site of perforation is above the muscle attachment, infection enters the canine space.
- **Maxillary premolar**—infection from the roots of premolars generally exits from the bone on buccal aspect and occasionally, on the palatal aspect. Because of the muscle attachments in the buccal region (zygomaticus major and minor and levator labii superioris), which are situated above the root apices of upper premolars, infection from these teeth will tend to localize within the oral vestibule. On the other hand, sometimes due to long roots of premolar, a canine space infection may develop.
- **Maxillary molars**—periapical infections from upper molars usually perforate the buccal aspect of the alveolar process, but on occasion, a palatal abscess may be encountered. The relationship of the attachment of buccinator muscle is the factor that determines whether localization is intraorally or extraorally. If the perforation occurs below, muscle swelling will appear intraorally and in reverse situation, infection extends laterally to buccinator muscle and form buccal space abscess.
- **Mandibular incisor**—it will reach labial aspect of the alveolar process. In this region, relationship of mentalis muscle to root apices of these teeth determines the further course of infection. If the infection breaks through the bone above mentalis muscle, swelling will appear in the vestibule. If the infection breaks through the bone below the attachment of the mentalis muscle, swelling will appear extraorally. It may remain localized in the subcutaneous tissues of chin or it may spread into the submental region.
- **Mandibular canine**—as the muscle attachments in the region of mandibular canine are located well below the apex of the tooth, periapical infection from this tooth will localize in the oral vestibule, after extending through the labial cortical plate.
- **Mandibular premolar**—infections from lower premolars penetrate the buccal cortex. The further extension is governed by depressor labii inferioris, depressor anguli oris and platysma. This results in vestibular abscess. Rarely, lingual cortical perforation may occur and result in sublingual abscess.

- *Mandibular first molar*—infection from lower first molar can also drain to buccal aspect of bone, below the attachment of the buccinator. The oblique line of buccinator muscle attachment on mandible, however, generally results in root apices being above the origin of this muscle thereby causing localization of infection within the oral vestibule.
- *Mandibular second molar*—due to the position of second molar in the alveolar process, there are 50% chances of perforation of the infection either buccally or lingually. There are equal chances of the root apices to be either above or below the attachments of the mylohyoid or buccinator. Hence there are 4 possible sites for localization of infection arising from these teeth:
 - On the buccal aspect abscess may either be form in the buccal vestibule.
 - It may appear in the buccal space.
 - On the lingual surface, exit of infection above mylohyoid will result in sublingual abscess.
 - Perforation below the mylohyoid muscle results in submandibular space involvement.
- *Mandibular third molars*—it is generally positioned medial to the vertical plane of ramus. Therefore, its apex is much closer to the buccal cortical plate. In this region, attachment of mylohyoid muscle is near the alveolar margin and its posterior border is just behind the tooth. Due to this relationship, infection from vertically positioned third molar will tend to involve the submandibular space. With mesioangularly and horizontally placed teeth the infection will tend to spread beyond the posterior extent of mylohyoid muscle and localize in pterygomandibular space. Occasionally, infection from third molars can involve the sub-masseteric space.

Spread of Infection

Direct Invasion or Extension (Table 19-1)

It is the propagation of an infection between the layers of fascia; from one area to fascia of another area. It can occur secondary to distension and pressure on the body. This will force contents of infection through facial layers by hydrostatic pressure.

- *Spread of infection within the bone*
 - *Alveolar bone*—the bone of the alveolar process is quite similar to the dental structure, in terms of response to infection. The alveolar bone consists of interconnecting marrow spaces delimited by unyielding calcified tissue, all of which are enclosed circumferentially by layers of cortical bone of varying thickness.
 - *Invasion of bacteria in marrow*—the invasion of bacteria from marrow space triggers the process of inflammation and cause some consequences of edema,

Table 19-1: Sites of localization of acute dental infections

Involved teeth	Usual exit from bone	Relation of muscle attachment to root apices	Site of localization
Upper central incisor	Labial	Above	Oral vestibule
Upper lateral incisor	Labial palatal	Above	Oral vestibule Palate
Upper canine	Labial	Above Below	Oral vestibule Canine space
Upper premolars	Buccal palate	Above	Oral vestibule Palate
Upper molars	Buccal Palatal	Above Below	Oral vestibule Buccal space Palatal
Lower incisors	Labial	Above Below	Submental space Oral vestibule
Lower canine	Labial	Below	Oral vestibule
Lower premolars	Buccal	Below	Oral vestibule
Lower first molar	Buccal Lingual	Below Above Below	Oral vestibule Buccal space Sublingual space
Lower second molar	Buccal Lingual	Below Above Below Above	Oral vestibule Buccal space Sublingual space Submandibular space
Lower third molar	Lingual	Above	Submandibular or pterygomandibular space
Involve teeth	Usual exist		

ischemia, necrosis and isolation from systemic circulation and immune system. This is the process by which bacteria survive within the bone of jaw.

- *Spread of infection*—the path of least resistance is along the medullary spaces. This explains the ability of odontogenic infection such as osteomyelitis, to spread for great distances along the jaw before they erode through the cortical plate. Another factor in the spread of infection within the bone is the thickness of the cortical plate on either side.
- *Spread in maxilla*—in maxilla, the buccal cortical plate is thinner as compared to the palatal; hence the abscesses erode through the buccal cortical plate.
- *Spread in mandible*—in mandible the buccal plate of bone over the bicuspid and molar is thick, while the lingual plate is thinner; hence the infection from lower

molar teeth spread lingually, eroding through the lingual cortical plate and then spreads into the soft tissues of floor of mouth.

- *Spread of infection within the soft tissues*
 - *Muscle and fascia*—muscle and fascia function as anatomic barriers to spread of infection within the soft tissues because muscles have tight dense capsule surrounding them and are well vascularized. They are more susceptible to bacterial invasion than loose connective tissue surrounding them. Muscles and fascia of head and neck are having potential space within which the invading bacteria can propagate for a while. This contain various organs including nerves and blood vessels, salivary glands, lymph nodes and fat with surrounding loose fibrous connective tissue. These are the pathways around which infections can spread.
 - *Stage of inoculation*—if the infection does not perforate the oral mucosa, it will enter the fascial spaces of head and neck region. For several days after their initial entry into the soft tissues the bacteria will grow without triggering an intense inflammatory response. A mild edema may be present in the affected area and the patient may experience soreness. This minor swelling can later become soft and doughy on palpation. This stage of infection responds quite well to either extraction or endodontic treatment of the offending tooth.
 - *Stage of cellulitis*—as the bacteria that have inoculated the soft tissue space multiply, they elaborate toxins and metabolic byproducts due to which, an intense inflammatory response is triggered.
 - *Stage of abscess*—as the cellular phase of inflammation progresses, inflammatory cells consisting of many polymorphonuclear leukocytes are drawn to the area of infection by various lymphokines, including leukotoxin. These phagocytes engulf the bacteria and digest them. Other lymphokines cause necrosis of the surrounding soft tissues.
 - *Resolution*—one or two days after the beginning of infection, specific immune system consisting of antibiotics and activated T lymphocytes come into play. This is called as ‘round cell infiltration’, consisting of lymphocyte macrophages and plasma cells. Macrophages are efficient in phagocytosis of bacteria and necrotic debris and are able to dispose off this material.

Spread by Lymphatic System

The face and neck infections result in regional lymph node enlargement, which results from proliferation of lymphocytes and histiocytes in response to antigenic stimulation.

If the antigen is catabolized and becomes non antigenic, the process of lymphocyte activation ceases and the nodes will return to their previous size.

Spread by Blood Vessels

The hematogenous spread of head and neck soft tissue infection may result in very serious complications such as bacteremia, resulting in distant infections involving the heart valve, and cardiac, vascular and orthopedic prosthesis. The microorganisms entering the vascular system may also result in thrombophlebitis, problems particularly involving the intracranial sinus, e.g. cavernous sinus thrombosis. Another serious consequence is generalized septicemia, which can result in shock and death.

Diagnosis of Odontogenic Infection

To arrive to an accurate diagnosis and for appropriate treatment, the basic principles of patient evaluation must be firmly observed. Proper patient evaluation is based upon:

- *Careful history including review of all systems*—the clinician should obtain history of the present illness as it relates to the onset, history of toothache and headache, nature, location and duration of pain, chills, etc.
- *Physical examination*—a comprehensive regional examination of the patient must include inspection, palpation and percussion. Size of the swelling and its relationship to the anatomic structures should be noted on inspection. Palpation is used to confirm the size, note tenderness, temperature and to assess regional lymph nodes and fracture. Percussion with metallic instrument is useful in determining periapical infections.
- *Appropriate laboratory studies*—sometimes a clinician may need to establish a diagnosis by laboratory confirmation, prior to any treatment. The investigations required while dealing with odontogenic infections may be complete blood count, blood sugar level, ESR, gram staining, culture and sensitivity, Montoux test, blood culture, biopsy, radiograph and computed tomography.
- *Proper interpretation of findings*—all these findings, complete history and examination should be properly interpreted then and diagnosis should be made.

Pathophysiology of Infection

- *Cardinal sign*—the body’s response to infectious agent is inflammatory, which is essentially a protective phenomenon. Hence, the cardinal signs of inflammation are present, to some degree, in nearly all patients with infection.

- *Redness (rubor)* is seen when the infection is close to the tissue surface, which is secondary to the intense hyperemia caused by increased vasodilation of arterioles.
- *Calor or heat* is due to inflow of relatively warm blood from deeper tissues, increased velocity of blood flow and increased rate of metabolism.
- *Dolor or pain* results from pressure on sensory nerve endings, from distension of tissues caused by edema or spread of infection. Release of substance like kinins, histamines or bradykinin is also responsible for pain. It is the most universal sign of infection.
- *Swelling* accompanies infection, unless the infection is confined to bone which cannot swell. It is due to the accumulation of fluid, exudate or pus.
- *Loss of function* is another sign of infection. A patient immobilizes the painful part in the most comfortable position he can find. Hence, when the masticatory muscles are involved, there is limitation of jaw movement.
- *Fever* occurs in some cases, which reflect a non-specific physiologic response of host to tissue injury. This injury results in increase of substance called pyrogen from endogenous (injured tissue) and exogenous source (infecting agent). In clinical fever, it appears that the hypothalamic regulating center is stimulated by endogenous pyrogen, which is activated by bacterial endotoxin release from granulocytes, monocytes and macrophages.

Principles of Management of Odontogenic Infection

The primary treatment of odontogenic infection does not end with extraction of offending tooth. It also includes establishment of adequate drainage and administration of appropriate antibiotics along with maintenance of airway, when indicated.

- *Proper assessment of airway*—often this becomes difficult due to limited mouth opening, which frequently accompanies these facial space infections. To assess it properly, mouth opening should be measured; tongue mobility and elevation of floor of mouth should be checked lateral pharyngeal edema and deviation of uvula should also be checked. If the airway compromise is recognized early, then an awake fibro-optic laryngoscopy or blind nasal intubation should be used. If intubation can not be performed while the patient is awake, tracheostomy should be considered.
- *Evaluation of vital parameters*—pulse, temperature and respiration should be recorded. If temperature is more than 103 degree Fahrenheit, then it is a cause of concern. In such cases, besides employing local and systemic

measures of lowering the temperature, culture of blood and urine should be done to check for septicemia and a radiograph must be taken for checking aspiration pneumonia.

- *Hydrate the patient*—most of the patients have poor oral intake for several days, secondary to dysphagia and pain. Fever also increases the metabolic requirements of a body. Intravenous hydration should be initiated and monitored by normalization of vital signs and urine output. Along with IV fluids, rich nutritional supplements can be given to improve the nutritional status.
- *Good clinical examination*—good clinical examination with proper history is very important. While taking history, assessment of pre-existing systemic conditions such as diabetes mellitus, tuberculosis should be done.
- *Empiric antibiotics therapy*—with serious infection it is often necessary to begin antibiotic therapy before the culture result is available. This is called as empirical therapy which is directed towards organisms most likely to cause that infection. Most often the empirical antibiotics of choice for oral infection are penicillin and for penicillin allergic patients, erythromycin should be given.
- *Incision and drainage*—it relieves pain and hastens resolution and healing. Ideally an abscess should be incised at its earliest sign of ripening, i.e. when only thin budging mucosa separates the scalpel from the infection. The incision should be located at a cosmetically and functionally acceptable place, such as under the shadow of jaw line or in a hair bearing area. Intraorally, the incision should be avoided at sites of oral function, such as labial frenum or depth of vestibule where the denture border may rest.

Sequelae of Pulpitis (Pulpopariapical Abscess)

- *Causes of pulpitis*—causes for pulpitis is due to irritating inflammatory products. Various factor like host resistance, number and virulence of bacteria, amount of antigenic material, and degree of tooth function and extent of other trauma also play a vital role.
- *Local inflammatory response*—these products escape from pulp canal and initiate local inflammatory response. The pulp is non-vital in such cases.
- *Periapical lesion*—if none of the irritating products of pulp necrosis reach the periapical tissue, then no periapical pathosis is induced. If infection reaches the periapical tissue then in some cases host defense effectively combats and localizes the resultant inflammation in circumscribe area.
- *Acute periapical abscess*—teeth with contaminated gangrenous pulp have large number of bacteria passing

in the root canal which may be sufficient to overwhelm the defence of periapical tissues resulting in an acute periapical abscess.

- *Chronic alveolar abscess*—resultant infection may be partially controlled by body defence, by surgically induced draining or by antibiotic therapy, thus results in the development of chronic periapical periodontitis or chronic alveolar abscess.
- *Radicular cyst*—odontogenic epithelial rests of Malassez (present in PDL and periapical granuloma) proliferate a radicular cyst may develop in response. If adequate root canal treatment is done, these will be ultimate disappearance of granuloma and complete resolution of radiolucency to normal bone.
- *Periapical scar*—if granuloma has been subjected to repeated exacerbation due to periodic contact with the irritation from root canal it may become fibrosed. If root canal treatment is done successfully, remaining inflammation and granulomatous tissue will resolve leaving only fibrosed areas behind. Such entities are referred to periapical scar.
- *Osteomyelitis*—if the infection is not controlled there are chances of infection that may turn into osteomyelitis.

Radiographic Considerations

- *Lamina dura*—there are variations in lamina dura from person to person and region to region. Lamina dura is not continuous in case of periapical pathology.
- *Amount of bone destruction*—30 to 60% bone destruction required for radiographically detectable changes. Radiographic changes can not be detected without involvement of junctional and cortical bone.
- *Root resorption*—external root resorption is caused by orthodontic movement, inflammation or infection of bone and benign and malignant tumor.

Etiology of Major Facial Infection

Teeth

- *Decay (caries)* reaching the dental pulp—pulpitis, this in turn spreads to supporting bone, resulting in periapical abscess, which in turn may spread subperiosteally.
- *Periapical abscess* may occur in seemingly intact but devitalized teeth (trauma, cracks or decay under fillings).
- Periapical and periodontal abscess may form as a result of chronic gingivitis and supporting bone and soft tissue loss (*periodontal disease*).
- *Erupting teeth* (especially partially impacted lower third molars) can result in inflammation and infection of the

soft tissue flap preventing eruption (operculum) with resultant swelling, pus, etc. around the crown (pericoronitis).

Jaws

- *Cyst and tumors*—it can develop *cysts or tumors* that can range from odontogenic to either primary or secondary malignancy. Most are derived from the dental apparatus and although benign, can nevertheless continuously grow and become secondarily infected on breaching the surrounding bone.
- *Osteomyelitis*, although rare, can be the result of chronic infection, as mentioned before.
- *Osteoradionecrosis* occurs readily in irradiated jaws subjected to further trauma (such as extractions).
- *Bacterial infection*—these are tuberculosis, actinomycosis and syphilitic osteomyelitis.
- Most *jaw fractures* in the tooth bearing segments are defined to be compound to the oral cavity and can easily be infected by the oral microbes.
- *Extraction sites*, again are comparable to compound fractures and it is surprising that infection in such cases are relatively rare.

Major Salivary Glands

It may be the subject of either viral or bacterial infections, often superimposed on obstruction of ducts (stones, stricture, etc). Tumors, rarely, also becomes secondarily infected.

Paranasal Sinuses

It may be primarily infected, obstructed and result in facial swelling. It may become infected, secondary to infected teeth protruding into the maxillary sinus (upper premolars and molars often exhibit close proximity to sinus). Tumors or cysts may become infected. Fractures such as the orbital floor, are by definition compound to the “exterior” and may result in orbital cellulitis.

Acute and Chronic Infections of Oral Cavity

Periapical Abscess

An abscess is a localized collection of pus, surrounded by an area of inflamed tissue in which hyperemia and infiltration of leukocytes is marked. Abscess can be caused by trauma or chemical or mechanical irritation. Due to trauma, there is bacterial invasion of dead pulp.

Types

- *Acute or symptomatic*—it is localized collection of pus producing symptoms of severe pain in the tooth.
- *Chronic or asymptomatic*—it is a long standing, low grade infection of the periradicular tissues. Symptoms of chronic infection are less severe.

Pathogenesis

- *Microorganism*—streptococci viridans and staphylococci are frequently associated with abscess formation. They produce the enzyme called coagulase which causes fibrin deposition and thus helps in walling off the lesion. Coagulase promotes virulence by inhibiting phagocytosis.
- *Bacterial invasion*—bacterial invasion of pulp canal takes place. Canal contains large number of virulent bacteria that rapidly spread to periapical tissues, causing acute periodontitis, tender tooth and alveolar swelling.
- *Necrosis of periapical tissue*—when inflammatory response may extend into adjacent periapical alveolar bone, it will initiate necrosis of periapical tissue.
- *Abscess formation*—necroses tissue coalesces and enlarges, compressing the surrounding fibrous connective tissue. Thus an abscess is generated, which is a collection of pus surrounded by a wall of fibrous connective tissue.
- *Progress of abscess*—enlarging dentoalveolar abscess contains purulent material that is under pressure due to the production of pus. The purulent material travels along path of least resistance, until it reaches the surface, where due to limitation of periosteal layer, it temporally forms subperiosteal abscess. Eventually, it erodes through the periosteum and penetrates the soft tissue, again, following the path of least resistance. Path of least resistance is determined by the location of breakthrough in the bone and the anatomy of muscles and fascia plane in the area.
- *Sinus formation*—well circumscribed lesion may form sinus due to:
 - Inability of the body to completely contain or localized the causative organisms.
 - Increase in number of causative organisms.
 - Lowering of patient's general resistance.
 - Trauma or surgical intervention.

Clinical Features

Acute periapical abscess

- *Location*—it develops in the periapical region of the tooth as sequelae to necrosis of pulp (**Fig. 19-1**).
- *Symptoms*—pain is severe and of throbbing type. Periapical abscess may confine to osseous structures

Fig. 19-1: Periapical abscess showing swelling in palatal surface.

and during the early period of abscess formation, may cause excruciating pain without observable swelling. The patient may appear pale, irritable and weak from pain, loss of sleep as well as from absorption of septic products. Patient may have slight fever (99 to 100° F).

- *Signs*—patients experience sensitivity or pressure in the affected area. Ice relieves the pain and heat intensifies it. Aspiration yields yellowish pus.
- *Positive tenderness*—the tooth becomes more painful, appears elongated and mobile. In acute periapical infection, tooth is sensitive to percussion and movement.
- *Lymph node involvement*—there is also painful lymphadenopathy.
- *Swelling*—swelling is usually seen in adjacent tissues adjacent to the affected tooth (**Fig. 19-2**). The tissues at the surface of swelling appear to be taut and inflamed.

Fig. 19-2: Swelling involve palatal surface and extending into mid palatal region.

The surface of tissue become distended from the pressure of underlying pus and finally ruptures due to pressure and lack of resistance caused by continued liquefaction.

- **Maxillary involvement**—when the maxillary anterior teeth are involved, swelling of upper lip may extend to one or both eyelids. When the maxillary teeth are involved, the cheek may swell to an immense size, distorting the patient's face. When the maxillary posterior teeth are involved, there is possibility of maxillary sinus involvement (**Fig. 19-3**).
- **Mandibular involvement**—when the mandibular posterior teeth are involved, swelling of the cheek may extend to ear.

Fig. 19-3: Palatal abscess (Courtesy Dr Bhaskar Patle).

Chronic periapical abscess

- **History**—history of pain that started as dull ache and progressed to severe throbbing type. Sudden decrease in pain signals the formation of sinus.
- **Signs**—vitality test is negative with involved tooth.
- **Sinus formation**—sinus opening appears as a small ulcer (**Fig. 19-4**), rough and may bleed easily. Occasionally, after temporary emphysema, sinus heals and form slightly raised pale papule. As the pus accumulates, another sinus formation may take place eventually.
- **Location of draining fistulas or sinus**—these are also commonly associated with chronic alveolar abscess. Majority of sinus or fistula opens on labial and buccal aspect of alveolus, as apices of both maxillary and mandibular teeth are located nearer to the buccal than the lingual cortical plate. In maxilla, roots of lateral incisors and molars are close to palatal cortical plate, so sinus can appear there. Most root tips lie below the mylohyoid muscle, so pus drains into the submandibular space.
- **Parulis**—at the opening of sinus, there is mass of inflamed granulation tissue. This is called as Parulis.

Fig. 19-4: Intraoral sinus formation seen in case of chronic periapical infection.

- **Cutaneous sinus**—in some cases, dental abscess may drain into overlying skins and drain via cutaneous sinus (**Figs 19-5A and B**).

Figs 19-5A and B: Cutaneous sinus showing extraoral opening.

- *Lymph nodes*—the patients will demonstrate lymphadenopathy as well.
- *Turner hypoplasia*—it is present in case when infection from deciduous teeth spread to the successor teeth resulting in hypoplasia of tooth.

Radiographic Features

Acute periapical abscess

- *Periodontal ligament space widening*—swelling of periodontal ligament space force the tooth slightly from its socket, creating widening of periodontal ligament space (Fig. 19-6).

Fig. 19-6: PDL space widening seen in acute periapical infection.

- *Unsharpness at the tooth apex*—after some period, the first change seen is usually of slight unsharpness of some of the trabeculae at the tooth apex.
- *Cortex destruction of developing follicle*—if acute alveolar abscess of deciduous teeth occurs, the possibility of damage to the permanent successor can occur which is evident by rarefaction produced by destruction of the cortex of the follicle.

Chronic periapical abscess

- *Lamina dura*—there is loss of thickness and density of the apical portion of lamina dura of the affected tooth (Fig. 19-7).
- *Periapical rarefaction*—widespread area of diffuse demineralization of the periapical bone, of affected tooth becomes apparent (Fig. 19-8).
- *Margins*—margins vary from well defined with possible hyperostotic borders to poorly defined, in chronic cases. In some areas, margins fade gradually and imperceptibly into the normal bone, while in some there is abrupt demarcation between the normal bone and the radiolucent area.
- *Advanced cases*—after some period, the trabeculae which are rarefied are destroyed and the dark area become darker and larger, as more of the surrounding bone is taken into the diseased area (Figs 19-9A and B).

Fig. 19-7: Chronic periapical infection in upper first molar showing loss of lamina dura (Courtesy Dr Ashok L).

Fig. 19-8: Periapical rarefaction seen in chronic periapical infection.

- *Adjacent tooth*—in some cases, radiolucency may involve adjacent tooth and there may be loss of lamina dura of that tooth.
- *Side of root*—in some cases, osteitis can occur at the side of root rather than the apex. The reasons for this are that the infection may spread from adjacent tooth or perforation of the root (while filling the canal) or from an aberrant canal opening.
- *Maxillary upper posterior teeth*—in case of maxillary upper posterior teeth (as they are near to maxillary sinus), the radiographic appearance shows bone destruction at the apex of the tooth, along with loss of lamina dura and with destruction of a portion of the antral floor.
- *Root*—roots of the affected teeth may show resorption.

Diagnosis

- *Clinical diagnosis*—positive tenderness, carious tooth, sinus formation, non-vital teeth will give clue to the diagnosis.

Figs 19-9A and B: Loss of bone density seen in periapex of the tooth due to chronic periapical infection.

- **Radiological diagnosis**—PDL space widening, loss of lamina dura and periapical rarefaction will diagnosed this condition.
- **Laboratory diagnosis**—central region of necrosis contain dense accumulation of polymorphonuclear leukocytes, surrounded by inflamed connective tissue wall of varying thickness.

Differential Diagnosis

- **Periodontal abscess**—it is an accumulation of pus along the root surface of a tooth. It is associated with periodontal pocket with mild pain. It is usually associated with vital, rather than pulp less teeth.
- **Periapical osteofibrosis**—it is associated with vital tooth. There may be persistence of lamina dura in the periapical osteofibrosis, even in the presence of well marked bone destruction.
- **Foramina**—in it, lamina dura is intact. If foramens are exactly superimposed on the roots, then

another radiograph should be taken at different angulation.

- **Inferior dental canal**—it is frequently superimposed on the lower molars and if the canal is dark and apex is small, it is difficult to trace the lamina dura. In this case, magnifying glass should be used to trace the continuity of lamina dura.
- **A large normal marrow space**—it can be confused if superimposed on the apex of the root. Again, by using magnifying glass, lamina dura can be traced.

Management

- **Establish drainage immediately, if possible**—it may be done by opening the pulp chamber and passing file through the canal into the periapical region. Trephination opening through mucosa and bore to the abscess at apex. Through and through drain is placed in the abscess and irrigated with 1:1 mix of 3% H₂O₂ and normal saline solution.
- **Antibiotics** like Penicillin 500 mg, QID, for 5 days and analgesics should be given.
- **Endodontic treatment**—in 24 to 48 hours, it can be determined if the tooth can be treated endodontically or extraction is necessary. If there is need of retention of offending tooth, necrotic pulp should be opened and tooth should be treated endodontically.
- **Warm saline mouth rinse** often aid in localizing the infection and maintaining adequate drainage, before endodontic treatment or extraction.
- **Extraction of teeth**—the tooth which can not be restored should be extracted.

Acute Apical Periodontitis

When the inflammatory degradation products from infected pulp penetrate, apically periodontal ligament in sufficient amount, inflammation is initiated. In this condition there is no frank abscess formation present. This will help to differentiated it with acute periapical abscess.

Etiology

- **Trauma**—it may occur due to occlusal trauma caused by abnormal occlusal contact or by recently inserted restoration beyond the occlusal plane.
- **Wedging**—wedging of foreign object between the tooth such as toothpicks, food or a sliver of rubber dam left by teeth can cause inflammation.

Clinical Features

- **Location**—inflammation is restricted to periodontal ligament.

- *Symptoms*—pain is of throbbing type.
- *Signs*—tooth is non-sensitive to hot, cold, sweet or sour food. Due to apical edema, tooth is elevated in the socket. It is very tender to pressure and percussion.

Radiographic Features

- *PDL space widening*—widening of periodontal ligament space is caused by edema (Fig. 19-10).

Fig. 19-10: Acute apical periodontitis seen with first molar (Courtesy Dr Ashok L).

Diagnosis

- *Clinical diagnosis*—tender tooth without abscess formation and secondary to trauma will give clue to diagnosis
- *Radiological diagnosis*—periodontal ligament (PDL) space widening is present.
- *Laboratory diagnosis*—an inflammatory reaction occurs in the apical periodontal ligament. The blood vessels are dilated. Polymorphonuclear leukocytes are present and an accumulation of serous exudate distends the periodontal ligament and extrudes the tooth slightly.

Management

- *Conservative management*—determine the cause and reliving the symptoms. When the acute phase is subsided, the tooth is treated by conservative means.

Acute Exacerbation of a Chronic Lesion

It is also called as '*phoenix abscess*.' It is an acute inflammatory reaction superimposed on an existing chronic lesion, such as on cyst or granuloma.

Etiology

The peri-radicular area may react to noxious stimuli form a diseased pulp with chronic peri-radicular disease. At times, because of an influx of necrotic product from a diseased pulp or because of bacteria and there toxins, this apparently dormant lesion may react and cause an acute inflammatory response.

Clinical Features

- *Symptoms*—patient complains of intense pain, local swelling and possibly associated cellulitis (Fig. 19-11).
- *Signs*—at the onset, tooth may be tender to touch.
- *Surface*—mucosa over the radicular area may be sensitive to palpation and may appear red and swollen.
- *History*—the patient has history of traumatic accident that turned the tooth dark after a period of time or of postoperative pain in a tooth that had subsided until the present episode of pain.
- *Vitality test*—lack of response to vitality test points to diagnose necrotic pulp.

Fig. 19-11: Local associated cellulitis occur in patient with phoenix abscess.

Radiological Features

Radiological features of this condition are same as that of chronic periapical infection (Fig. 19-12).

Diagnosis

- *Clinical and radiological diagnosis*—positive tenderness with radiological finding of chronic periapical infection will diagnose this condition.
- *Laboratory diagnosis*—area of liquefaction necrosis with disintegrating polymorphonuclear neutrophils and cellular debris. These are surrounded by infiltration of macrophages and some lymphocytes.

Fig. 19-12: Phoenix abscess showing same appearance as that of chronic periapical abscess.

Differential Diagnosis

- *Acute alveolar abscess*—vitality test; it will react to electrical pulp test and application of cold, as compared to acute exacerbation of chronic infection.

Management

- *Drainage*—either via the root canal or by incision, if there is localized swelling.
- *Antibiotics and anti-inflammatory drugs*—this should be given to the patient.

Pericoronal Abscess

It is also called as '*pericoronitis*'. It is the infection of soft tissues surrounding the crown of a partially erupted tooth.

Clinical Features

- *Location*—the most common type of pericoronal infection is found around the mandibular 3rd molar.
- *Symptoms*—pain, malaise is present. Pain may radiate to throat, ear or floor of mouth.
- *Sequelae of pericoronitis*—it may result in cellulitis and muscular trismus. There is also regional lymphadenopathy, submaxillary and pharyngeal abscess.
- *Signs*—operculum may get traumatized by opposing teeth during mastication (**Figs 19-13 and 19-14**). Edema, visible in both submandibular area and peritonsillar region. There is extreme tenderness on palpation of the abscess.
- *Pericoronal infection of infancy*—pericoronal infection of infancy is often associated with the supra-dental tissue, involving the superior portion of the follicle and the overlying mucoperiosteum, which may become

Fig. 19-13: Pericoronitis affecting partially erupted third molar.

inflamed. It ultimately develops into small fluctuant abscess. When this fluctuance is digitally ascertained, incision and drainage should be carried out, followed by warm saline rinses at frequent intervals.

- *Complication*—the involvement may become localized in the form of a pericoronal abscess. It may spread posteriorly into the oro-pharyngeal area and medially, to the base of the tongue. Peritonsillar abscess, cellulitis and Ludwig's angina are common.

Fig. 19-14: Pericoronitis showing inflammation of operculum around the third molar.

Radiographic Features

- *Appearance*—defect in bone on mesial or distal side which appears as the step like distortion of crypt wall distal to the crown (**Fig. 19-15**).
- *Lower 3rd molar area*—in cases of lower third molar, there is circumferential bone resorption around the tooth.

- *Sclerosing osteitis*—follicular crypt may show sclerosing osteitis. Generalized thickening of the wall of crypt indicates low-grade infection.
- *Semilunar shaped bone resorption*—mesially tipped impaction display semilunar shaped bone resorption mesial to the crown and in cases of distally placed impaction, it is distal to the crown.

Fig. 19-15: Distal bone loss seen in association with 3rd molar suggestive of pericoronitis.

Diagnosis

- *Clinical diagnosis*—inflammation of pericoronal tissue around 3rd molar with pain and trismus will give clue to the diagnosis.
- *Radiological diagnosis*—there is semilunar shaped distal bone loss.

Management

- *Antibiotics*—immediately, antibiotics should be started. Most commonly use antibiotics are phenoxymethyl penicillin 250 mg four times daily. In pericoronitis due to ulceromembranous gingivitis metronidazole 200 gm three times daily for 7 days is given.
- *Drainage*—careful probing should be done around the 3rd molar, which permits entry into the expanded follicle and allows evacuation of pus and other septic material.
- *Extraction*—when the symptoms become sub-acute, the impacted 3rd molar should be extracted.
- *Operculectomy*—sometimes when the retention of 3rd molar is necessary, the inflamed tissue surrounding the occlusal portion of the tooth should be excised.
- *Extraction of maxillary 3rd molar*—maxillary 3rd molar can be a contributing factor to the pericoronal infection of the mandibular 3rd molar. In such cases, especially when the mandibular 3rd molar is fully erupted in

proper place, the maxillary 3rd molar should be extracted prior to the retention of the mandibular 3rd molar, considering the recurrent nature of the inflammatory episode.

Superficial Abscess

The yellow color is imparted by accumulation/pooling of pus in the enlarging abscess, covered by thin, stretched skin (**Fig. 19-16**). Fistula, if formed, drains the pus and no yellow color will be imparted.

It appears as raised sessile swelling with smooth, frequently reddened mucosa, over yellow pus. The most common presenting symptoms, is pain which may be slight or severe. Fluctuant swelling and when aspirated, yield pus. Surface may be ulcerated.

Fig. 19-16: Superficial infection of the facial tissue showing covered by stretched mucosa.

Cellulitis

It is also called '*Phlegmon*'. Occasionally, the infectious process progress out of the bone, despite the use of supportive therapy and the patient develops cellulites, either in vestibular region or extraorally. It is a potential complication of acute dental infection.

Cellulitis may be defined as a non-suppurative inflammation of the subcutaneous tissues extending along the connective tissue planes and across the intercellular spaces. It occur when abscess is not able to drain through surface of skin.

Bacteriology

- *Hemolytic streptococci*—the alpha hemolytic streptococci are the classic etiologic agent. They produce enzymes like streptokinase and hyaluronidase. These enzymes break down fibrin, connective tissue ground substance and cellular debris, thus facilitating rapid spread of bacterial invaders.

Fig. 19-17: Cellulitis showing diffuse involvement of buccal space.

Clinical Features

- *Symptoms*—there is widespread swelling, redness and pain without definite localization.
- *Signs*—there is presence of tenderness on palpation. Tissues are grossly edematous. There is marked induration, hence tissues are firm to hard on palpation. Tissues are often discolored; temperature is elevated with malaise and lethargy. Usually massive cellulitis (Fig. 19-17) will ultimately suppurate, particularly if bacteria are staphylococcal.
- *Evacuation of pus*—depending upon the location and proximity to anatomic structures that guide the progress, the pus may evacuate into nose, maxillary sinus, and oral vestibule, floor of mouth, infra-temporal fossa and into fascial spaces.
- *Maxillary infection*—infections arising in maxilla may perforate the outer cortical layer of bone, above the buccinator attachment and, cause swelling of upper half of face. If infection in mandible perforates the outer cortical palate, below the buccinator attachment, there is diffuse swelling of the lower half of face, which then spreads superiorly as well as cervically.
- *Eye*—if maxillary tooth is involved, there may be redness of eye (Fig. 19-18).

Diagnosis

- *Clinical diagnosis*—diffuse edematous swelling with positive tenderness will give clue to diagnosis.
- *Laboratory diagnosis*—ESR and white cell count are raised. Biopsy shows diffuse exudation of polymorphonuclear leukocytes and occasional lymphocytes, with considerable serous fluid and fibrin, causing separation of connective tissue or muscle fibers. It presents only a nonspecific picture of diffuse acute inflammation.

Fig. 19-18: Maxillary infection showing orbital involvement.

Management

- *Surgical incision and drainage*—it is performed when the presence of pus is diagnosed. In case of large cellulites, a superficial erythematous spot develops, which is pathognomonic of pus near the superficial surface. These superficial fluctuant areas can be incised and drained under local anesthesia. Usually ring block of peripheral skin, as a wheel is made for skin anesthesia. Knife is introduced in the most inferior portion of the fluctuant area. A small sinus forcep is introduced in the wound, opened in several directions and pus is drained. A rubber drain is placed in the deepest portion of the wound, so that just 12 cm lie above the source of the skin, where it is sutured. A large dressing is applied. When no superficial spot is present, fluctuance is more difficult to determine, particularly if deep pus is suspected.
- *Antibiotics*—heavy antibiotics should be given to the patient. Usually antibiotics in the cephalosporin family should be given.
- *Extraction*—extraction of the offending tooth should be carried out.

Ludwig's Angina

It is a condition which was first described by Ludwig in 1936. The word angina means sensation of choking or suffocation. It is the most commonly encountered neck space infection.

It is a rapidly swelling cellulitis of the sublingual and submaxillary spaces, often arising from infection of the

tooth roots (molars and pre-molars) that extend below the mylohyoid line of the mandible.

This condition may be defined as an overwhelming, rapidly spreading, septic cellulitis involving submandibular, submental and sublingual spaces bilaterally.

Etiology

- *Odontogenic infection*—it is usually an extension of odontogenic infection from mandibular molar teeth into the floor of mouth. The 2nd and 3rd molars are the teeth most commonly involved.
- *Trauma*—it may also be caused by oral soft tissue laceration and punctured wounds of the oral floor.
- *Sialadenitis*—submandibular gland sialadenitis and infected malignancy may be sometimes contributory to Ludwig's angina.
- *Calculi*—salivary calculi or from intravenous injection of the internal jugular vein, especially in drug abusers.
- *Osteomyelitis*—osteomyelitis in compound mandibular fracture.

Bacteriology

Streptococci are the most commonly reported organism from the culture. Other microorganisms are α -hemolytic streptococci, bacteroides, *Klebsiella*, *Fusiform bacilli* and *E. coli*.

Clinical Features

There are three typical appearances of Ludwig's angina.

First

- *Brawny induration*—it is characterized by brawny indurations. Tissues are board like and do not pit on pressure. No fluctuation is present.
- *Gangrenous tissue*—the tissues may become gangrenous and when cut, they have a peculiar lifeless appearance.
- *Limitation between infected and normal tissue*—a sharp limitation is present between the infected tissues and surrounding normal tissues.

Second

- *Spaces involve*—three facial spaces are involved bilaterally, i.e. submandibular, submental and sublingual. If the involvement is not bilateral, the infection is not considered a typical Ludwig's angina.

Third

- *Open mouth and respiratory obstruction*—the mouth is opened (**Fig. 19-19**) and the tongue is lifted upwards and backwards, so that it is pushed against the roof of the mouth and the posterior pharyngeal wall; when this occurs, acute respiratory obstruction is likely to occur.

Fig. 19-19: Typical open mouth appearance seen in Ludwig's angina patient.

Other Features

- *Signs*—swelling is firm, painful and diffused, with no sign of localization. Floor of mouth appears erythematous and edematous. Stiffness in tongue movement generally develops. The patient develops a toxic condition and speech becomes impaired. Larynx and glottis become edematous. As the disease continues the swelling starts involving the neck.
- *Symptoms*—the patient always has fever and there is considerable salivation, as the patient is unable to swallow. There are chills accompanied with fever. There is an inability to swallow and to eat. Respiratory distress is common. There is also neck pain, redness of neck, weakness, fatigue, excessive tiredness, confusion or other mental changes, difficult breathing and earache. There is an intense pain on tongue movement and the patient may be severely dehydrated, owing to inability to take anything by mouth. If the swelling has spread into the pterygoid region, then there is difficulty in opening the mouth.
- *Woody tongue*—due to involvement of sublingual space, there is elevation, posterior enlargement and protrusion of tongue. This is called as woody tongue.
- *Bull neck*—there is enlargement and tenderness of neck above the level of hyoid bone due to submandibular gland involvement. This is called as bull neck (**Fig. 19-20**).

Fig. 19-20: Bull neck seen in Ludwig's angina patient (Courtesy Dr Bhaskar Patle).

Fatal Complications

- *Respiratory obstruction*—the infection of Ludwig's angina tends to spread through the connective tissues which cover the small muscles of the larynx and between the muscles of the floor of mouth. The epiglottis and larynx become edematous along with the posterior aspect of the tongue. The tongue gets elevated and gets pressed upward and backward, causing pressure on the larynx. Therefore, dyspnea occurs in paroxysm. Ultimately, death occurs due to respiratory embarrassment.
- *Generalized septicemia*—this can occur due to spread of infection.
- *Erosion of the carotid artery*—late spread of infection to lateral pharyngeal space can also cause erosion of the carotid artery.
- *Cavernous sinus thrombosis* with subsequent meningitis may be sequelae of it.
- *Others*—mediastinum extension, pharyngomaxillary space extension, osteomyelitis and airway obstruction.

Diagnosis

- *Clinical diagnosis*—open mouth appearance, woody tongue, bull neck and involvement of three spaces will diagnose this condition.
- *Laboratory diagnosis*—a moderate leukocytosis is found. Fusiform bacilli and spiral forms, various staphylococci, diphtheria and many other microorganisms have been cultured on different occasions.

Management

- *Intense and prolonged antibiotic therapy*—high dose penicillin is to be administered IM or IV, in high doses, because it is the empirical antibiotic of choice and the oral flora, including most of anaerobes, are sensitive to

it. Recently, combination of gentamicin and cloxacillin has been proved to be successful. In case of person who is resistant to penicillin, clindamycin, aminoglycoside and chloramphenicol can be given.

- *Establishment and maintenance of an adequate airway are the essentials of therapy*—tracheostomy is a routine procedure, but it is often difficult to perform in the late stages. Attempt at blind intubations is often time consuming. Recently, successful intubations with fiberoptic laryngoscope have been introduced as a worthwhile technique in the therapy of Ludwig's angina. In the late stage, cricothyroidotomy may be performed as an emergency procedure. Nowadays, administration of corticosteroids allows more rapid penetration of antibiotics and protection of airway. Most commonly used corticosteroid is intravenous dexamethasone should be given.
- *Incision and drainage*—it is done to release the tissue tension. A horizontal incision, midway between the chin and hyoid bone, is a classic approach to surgical drainage of Ludwig's angina. It may be carried out under local anesthesia.
- *Supportive therapy*—parenteral hydration, high protein diet and vitamin supplements.
- *Extraction of offending tooth*—extraction of offending tooth should be carried out.
- *Prevention*—regular visits to the dentist and prompt treatment of oral/dental infections can prevent the conditions that increase the risk of developing Ludwig's angina.

Impetigo

It is also called as 'non-bullous impetigo' or 'impetigo vulgaris'. It is acute superficial, purulent infection of the skin. It is caused by *Streptococcus pyogenes*.

Predisposing Factors

- *Poor oral hygiene*—this will lead to growth of organisms.
- *Living condition*—crowded living conditions and hot and humid climate is also responsible for impetigo.
- *Pre-existing disease*—pre-existing eczema and scabies and previous trauma and insect bite may also lead to impetigo.
- *Reduced resistance*—reduced resistance due to preceding influenza or herpes simplex infection.

Clinical Features

- *Age*—the disease is mainly seen in pre-school children and young adults.
- *Locations*—the face (angle of mouth, lips and nose) is the most common location.

- **Onset**—the lesions frequently begin as red, itchy spots.
- **Stuck on appearance**—the close set, round or oval, flat, pustular vesicles with a characteristic stuck on appearance subsequently develop.
- **Signs**—the thin roofed vesicle then burst to form golden yellow crust and some of the lesions may become confluent (**Fig. 19-21**).

Fig. 19-21: Impetigo showing rupture vesicle with some of them become confluent (Courtesy Dr Pincha).

- **Others**—the surrounding skin is erythematous with lymphadenopathy, which becomes tender.
- **Clinical pattern**—two clinical patterns are present. First is fragile vesicle which quickly ruptures (**Fig. 19-21**) and are replaced by thick adherent amber crusts and second long lasting bullous lesion.

Diagnosis

- **Clinical diagnosis**—red itchy sopt with typical stuck on appearance is characteristic of impetigo.

Management

- **Antibiotics**—single injection of long acting penicillin and 3-4 gm of oral penicillin V, daily, for 10 days. Alternate antibiotics which can be used are clindamycin, cephalexin and dicloxacillin.
- **Topical mupirocin**—it is effective treatment of choice.

Erysipelas

It is an acute, superficially spreading infection of the dermis, usually of the face, with a well demarcated, slightly indurated erythema and progressive lymphangitis. It is caused by Beta hemolytic streptococci. It is sometime also called as 'saint Anthony's fire' (as the wall of Saint Anthony's fire is that of same color of erysipelas).

Etiopathogenesis

- **Entry of microorganism**—the microorganisms are thought to enter the tissues through a small break in the mucosa or the skin, such as fissure, abrasion, erosion or excoriation.
- **Post-surgical erysipelas**—post-surgical erysipelas is caused by transmission of streptococci from the nose, throat, or hands of the patient or from, the attendant or visitors.
- **Predisposing factors**—nephrotic edema, lymphedema, dysgammaglobulinemia, malnutrition and alcoholism are known predisposing factors.

Clinical Features

- **Age and sex**—the newborn and infants are highly susceptible, but elderly are also affected. It is more common in women in 5th decade and in men, in 7th decade.
- **Location**—the most common location is on abdomen, face, scalp and legs.
- **Incubation period**—the incubation time it thought to be from few hours to several days.
- **Prodromal phase**—after short prodromal phase, characterized by malaise, vomiting, headache, pyrexia and chills. Erysipelas begins abruptly with a local sensation of burning and itching.
- **Symptoms**—the general condition of the patient worsens with toxemia, high fever, insomnia and restlessness.
- **Signs**—a small area of the skin then becomes intensely red and swollen (**Fig. 19-22**). Subsequently, bright red plaques develop and spread rapidly. Blisters, which break down to form large ulceration, may develop on the red lesion.
- **Margins**—the lesion has an elevated, edematous, sharp border and an irregular outline.
- **Lymph nodes**—regional lymph nodes become enlarged and tender.

Fig. 19-22: Red erythematous skin seen on the right cheek (Courtesy Dr Sanjay Pincha).

Oral Manifestations

- *Location*—it is uncommon in oral, pharyngeal and nasal mucosa. Erysipelas which develops in the oral, pharyngeal or upper respiratory tract mucosa result in the same constitutional reaction, as described for skin lesion.
- *Symptoms*—there is severe local pain, redness and swelling.
- *Signs*—edema may involve the tongue, uvula, epiglottis and may lead to serious consequences.
- *Lymph nodes*—the submandibular lymph nodes become markedly tender and swollen.

Diagnosis

- *Clinical diagnosis*—high fever with red and swollen skin with lymphadenopathy will aid in diagnosis.

Management

- *Antibiotics*—penicillin is the drug of choice and if sensitive to penicillin, erythromycin can be given.

Pyostomatitis Vegetans

It is an uncommon inflammatory disease of the oral cavity. It is unusual oral expression of inflammatory bowel disease. The name is given as there is a similarity between it and the skin lesions in a dermatologic disease known as pyodermitis vegetans. It may occur due to intestinal disturbances.

Clinical Features

- *Age and sex*—it occurs in any age with no sexual predilection.
- *Site*—this lesion may occur in any area of oral cavity, except in tongue. It is multiple in numbers.
- *Appearance*—oral lesions consists of large number of broad base papillary projections, tiny abscess or vegetations developing in areas of intense erythema.
- *Symptoms*—it painless but in some cases, oral discomfort may be present.
- *Signs*—these small projections are red or pink in color, but on careful examination may show tiny pustules beneath the epithelium, which liberate a purulent material when ruptured. Buccal and labial mucosal lesions have many folds and papillary projections may develop on these folds.
- *Snail track ulceration*—after vesicle is rupture ulceration is present which may coalesce into larger areas of necrosis.
- *Cobblestone appearance*—buccal mucosa show 'cobblestone' appearance, while vestibular lesions

appeared as folds and ulcers, the lips are diffusely swollen and indurated, gingival and alveolar mucosal lesions are granular with erythematous swelling and palatal lesions appear as multiple aphthous ulcers.

Diagnosis

- *Clinical diagnosis*—snail track ulceration with cobblestone appearance may give clue to the diagnosis.
- *Laboratory diagnosis*—biopsy shows papillary projections with tiny areas of focal necrosis and micro abscess formation, either intraepithelial or sub-epithelial.

Management

- *Sulfa drugs*—It is found that the oral lesions are regressed when the intestinal disturbance is brought under control. Medical management with sulfasalazine can be helpful in clearing the lesion.
- *Corticosteroids*—systemic steroids like prednisone is given in tapering doses. It is not specific.
- *Other therapy*—other therapy like fluocinonide gel and colectomy can be carried out.

Maxillary Sinusitis

It is described in chapter of paranasal sinus.

Chronic Hyperplastic Pulpitis

It is also called as 'pulp polyp' or 'pulpitis aperta'. It is essentially an excessive, exuberant proliferation of chronically inflamed dental pulp tissue.

Etiology

- *Slow carious exposure*—slow progressive carious exposure of the pulp is the cause.
- *Chronic low grade infection*—for the development of a hyperplastic pulp, a large open cavity, a young resistant pulp and a chronic low grade stimulus is necessary.
- *Mechanical irritation*—mechanical irritation from chewing and bacterial infection often provides the stimuli.

Clinical Features

- *Site*—teeth most commonly involved are deciduous molars and first permanent molars as they have an excellent blood supply because of a large root opening, and this coupled with high tissue resistance and reactivity in young person's accounts for unusual proliferative properties of the pulp tissue.
- *Age*—it is seen only in teeth of children and young adults.
- *Symptoms*—it is asymptomatic and there may be feeling of pressure when masticator forces are applied.

- **Appearance**—polypoid tissue appears as a fleshy, reddish pulpal mass filling most of the pulp chamber (**Fig. 19-23**) or cavity or even extending beyond the confines of the tooth.
- **Signs**—some times, mass if large enough interferes with comfortable closure of teeth. Polypoid tissue is less sensitive than normal pulp tissue and more sensitive than the gingival tissue. This tissue bleeds easily because of rich network of blood vessels.
- **Thermal testing**—the tooth may respond feebly or not at all to the thermal test.

Fig. 19-23: Chronic hyperplastic pulpitis presenting as reddish mass in third molar region (Courtesy Dr Tapasya).

Radiographic Features

It will show a large open cavity with direct access to the pulp chamber.

Diagnosis

- **Clinical diagnosis**—Fleshy pulpal mass in pulp chamber with negative thermal test will aid in diagnosis.

Differential Diagnosis

- **Proliferating gingivitis**—one should raise and trace the stalk of the tissue back to its origin, i.e. the pulp chamber.

Management

- **Pulp extirpation**—elimination of polypoid tissue, followed by extirpation of the pulp. After removing the hyperplastic tissue, bleeding can be controlled by pressure.
- **Extraction**—extraction of tooth can also be done.

Periapical Granuloma

It is the most common type of pathologic radiolucency encountered in dentistry. It is a growth of granulation

tissue continuous with the periodontal ligament resulting from the death of the pulp and diffusion of bacteria and bacterial toxins from the root canals into the surrounding periradicular tissues through the apical and lateral foramina.

It is the result of a successful attempt by the periapical tissues to neutralize and confine the irritating toxic product that is escaping from the root canal. But continuous discharge into the periapical tissues induces a vascular inflammatory response.

Etiopathogenesis

- **Prolonged irritation**—it occurs as a response to intense and prolonged irritation from infected root canals producing extension of chronic apical periodontitis beyond the periodontal ligament.
- **Release of inflammatory mediators**—insult from diseased pulp represents broad spectrum of inflammatory mediators like prostaglandins, kinin and endotoxins. Elevated level of IgG in pulpoperiapical lesion.
- **Replacement of bone by granulation tissue**—the expanding inflammation and increased vascular pressure result in abscess formation and resorption of the bone in the affected area, which in period of time is replaced by granulation tissue.

Clinical Features

- **Symptoms**—mild pain can be occasionally experienced while biting or chewing on solid foods.
- **Signs**—tooth may be darker in color, because of the blood pigments that diffuse into the dentinal tubules. There is, seldom, swelling or expansion of the overlying cortical bone. Tooth may feel to be slightly elongated in the socket.
- **Vitality test**—the tooth is non-vital, i.e. it does not respond to thermal and electric pulp test.
- **Sensitivity**—sensitivity occurs due to hyperemia, edema and inflammation of the apical periodontal ligament.

Radiographic Features

- **Lamina dura**—periapical area is radiolucent with loss of lamina dura (**Fig. 19-24**).
- **Size**—radiolucency is less than 1.5 cm in diameter (**Fig. 19-25**).
- **Margins**—there may or may not be hyperostotic borders. It may or may not have well defined borders.
- **Teeth**—involved tooth may show a deep restoration, extensive caries, fracture or a narrow pulp canal with non-vital pulp.
- **Multiple periapical granuloma**—in some cases, multiple periapical granuloma may be present (**Fig. 19-26**).

Fig. 19-24: Periapical granuloma presented as radiolucency in the periapex of tooth.

Fig. 19-25: Periapical granuloma presenting as radiolucency in relation with two teeth.

Fig. 19-26: Multiple periapical granulomas seen at the apex of the tooth.

Diagnosis

- *Clinical diagnosis*—it is not possible to make clinical diagnosis on the basis of signs and symptoms.
- *Radiological diagnosis*—well defined radiolucency less than 1.5 cm will go in favor of periapical granuloma.
- *Laboratory diagnosis*—biopsy shows proliferating endothelial cells capillaries, young fibroblasts minimum amount of collagen and occasionally, nests of odontogenic epithelium, Russell's bodies, foam cells and cholesterol clefts.

Differential Diagnosis

- *Osteolytic stage of Cementoma*—in case dental granuloma, tooth is non-vital.
- *Radicular cyst*—it is described in differential diagnosis of radicular cyst.
- *Surgical defect or periapical scar*—tooth shows root canals filling.

Management

- *Root canal therapy*—root canal therapy is treatment of choice.
- *Extraction of teeth*—if the tooth is unrestorable then extraction of the involved tooth should be carried out.
- *Curettage*—curettage of apical tissue can be carried out.
- *Causes of failure of treatment*—lesion may heal due to inadequate endodontic, vertical foreign material, associated periodontal disease, and cysts formation.

Periapical Scar

It is a possible end point of healing. It is composed of dense fibrous tissue and is situated at the periapex of pulp less tooth, in which usually, the roots canal have been successfully filled.

Formation of Scar

- *Irritant substance*—confined in the periapical area, which leads to accumulation of chronic inflammatory cells.
- *Granuloma formation*—young fibroblasts, endothelial cells and capillaries proliferate, which lead to granuloma formation.
- *Scar formation*—after endodontic treatment, the granuloma resolves, but in some cases, granulation tissue gets slowly organized with the production of more and more collagen fibers, which in turn leads to scar formation.

Clinical and Radiological Features

- *Location*—it is more common in anterior region of maxilla.
- *Tooth*—tooth is non-vital and the patient is asymptomatic.

Fig. 19-27: Periapical scar seen as radiolucency at the apex of central incisor (Courtesy Dr Mody).

- **Radiolucency**—well circumscribed radiolucency that is more or less round and is smaller than granuloma and cyst (**Fig. 19-27**).
- **Size**—scar is constant in size throughout the period.

Diagnosis

- **Clinical diagnosis**—it is not possible to make clinical diagnosis.
- **Radiological diagnosis**—radiolucency at the apex of endodontically treated tooth.
- **Laboratory diagnosis**—biopsy shows spindle shaped fibroblast scattered throughout the dense collagen bundles, which show advanced degree of hyalinization.

Management

There is no treatment necessary for this disease

Osteomyelitis

Osteomyelitis is the inflammation of the bone marrow that produces clinically apparent pus and secondarily affects the calcified components. It is infection of the bone that involves all the three components viz. periosteum, cortex, and marrow.

It may be defined as an inflammatory condition of the bone that begins as an infection of medullary cavity and the haversian system and extends to involve the periosteum of the affected area.

Predisposing Factors

Certain predisposing factors play an important role in the onset and severity of the osteomyelitis, in addition to the virulence of microorganism.

- **Conditions affecting host resistance**—condition like diabetes mellitus, tuberculosis, severe anemia, leukemia, agranulocytosis, acute illness such as influenza, scarlet fever, typhoid and exanthematous fever, sickle cell anemia, malnutrition, and chronic alcoholism will affect host resistance. This will predispose for osteomyelitis occurrence.
- **Condition affecting jaw vascularity**—metastasis from remote area of infection such as another bony site, skin and kidneys, radiation, osteoporosis, osteopetrosis, fibrous dysplasia, bone malignancy, and peripheral vascular disease will affects jaw vascularity.

Etiology

- **Odontogenic infections** which can be periapical or periodontal infection, pericoronal infection and infection from infected dental cyst.
- **Compound fractures of the jaws**—generally, these fractures are compound through the tooth socket into the mouth and rarely, to the skin.
- **Traumatic injury**—local traumatic injury of the gingiva leads to periostitis, in patients with low resistance to infection and later to osteomyelitis.
- **Middle ear infection and respiratory infection**—via hematogenous route, either from middle ear infection or from infection of the upper respiratory tract.
- **Furunculosis of chin**—furunculosis of chin, i.e. spread through lymphatic channel via infected lymph nodes.
- **Peritonsillar abscess**—peritonsillar abscess has also been reported to cause osteomyelitis of the ramus of mandible.

Pathogenesis

- **Compromised blood supply** is a critical factor in the establishment of osteomyelitis.
- **The virulent microorganisms** get entry in the medullary cavity via many routes like odontogenic infections, compound fractures, periostitis, hematogenous route and lymphatic channel.
- **Inflammatory reaction**—these microorganisms cause intense inflammatory reaction within the marrow of the bone. Pain is a feature of this stage.
- **Localization of infection**—most of the odontogenic infections, like periapical and periodontal infections, are localized by pyogenic membrane or soft tissue abscess walls.
- **Disorganization of clot**—however, disorganization of this pyogenic membrane occurs by virulent microorganism

or by chronic movement of the unreduced fractures of jaws.

- **Mechanical trauma**—mechanical trauma, due to chronic movement of unreduced fractures, burnishes the bone and causes ischemia, thereby introducing the microorganisms deep into the underlying tissues.
- **Accumulation of pus**—when this protective barrier breaks, the pus accumulated in the medullary cavity gives rise to increased intra-medullary pressure, which results in compression of vasculature, vascular collapse, venous stasis and ischemia.
- **Elevation of periosteum**—pus travels through the Haversian and Volkmann's canals and accumulates beneath the periosteum, elevating it from the cortex, thereby further reducing the blood supply.
- **Necrosis of bone**—the reduced blood supply leads to slow necrosis of the bone.
- **Penetration of periosteum**—if the pus continues to accumulate, the periosteum is penetrated and mucosal and cutaneous fistulae develop and thereby discharging the purulent pus.
- **After therapy**—as the therapy begins to be effective and the host resistance increases, the process become chronic. Inflammation regresses, granulation tissue forms and new blood vessels are formed which cause lysis of bone; thus causing fragments of necrotic bone from the viable bone.
- **Involucrum**—small sections of necrotic bone may be completely lysed, while large one get localized and get separated from the shell of the new bone by a bed of granulation tissue. This dead bone surrounded by viable bone is called involucrum.
- **Sequestra**—small pieces of necrotic bone are called as sequestra, which are avascular and which harbor microorganisms. These sequestra need to be removed, otherwise they continue to be chronically infected and infect the surrounding granulation tissue and cause further sequestration, which weakens the bone and may cause pathologic fracture.
- **Cloacae**—an involucrum contains one or more holes on the surface which lead into channels, which can be traced to end in the depth of the bone at the site of an area of bone destruction around the sequestrum. These orifices are termed 'cloacae'. Pus finds its way from the depth of the bone to the surface, through the cloacae. The presence of cloacae indicates that there is a dead bone or a foreign body at the deep end.
- **Systemic spread of infection**—besides the pathogenic activity of the virulent microorganisms, these microorganisms precipitate thrombi formation by virtue of their destructive lysosomal packages. The coagulum provides the host medium for further pathogenic proliferation as well as an isolating barrier from the host immune response. It also allows systemic spread of infection.
- **Necrosis of bone**—the necrosis of bone is brought about by thrombosis of the vessels or compression of the vasculature. The necrosis of bone, with superadded infection forms a base line pathogenesis of the osteomyelitis. Compression of neurovascular bundles can result in osteomyelitis mediated anesthesia. The possibility of pre-existing predisposing factors can further complicate this phenomenon.
- **Remodeling**—after complete removal of sequestra and resolution of disease process, the jaw undergoes complete remodeling.

Microbiology of Osteomyelitis

- **Microorganism**—microorganism responsible for osteomyelitis are *Staphylococcus aureus*, *Staphylococcus albus*, hemolytic streptococci, gram-negative organisms like *Klebsiella*, *Pseudomonas*, *Protease*, *E. coli*, anaerobic microorganisms like pepto-streptococci, bacteroides and fusobacteria. Some specific forms like *Mycobacterium tuberculosis*, *Treponema palladium* and *A. israeli*.
- Following parameters should be used for recognition of pure anaerobic or mixed anaerobic infection:
 - Presence of foul smelling exudate.
 - Sloughing of necrotic tissues or gas in the necrotic tissue.
 - Gram stain revealing multiple organisms of different morphological character.
 - Presence of sequestra.

Classification

- **According to anatomic location of infectious process**
 - Intramedullary
 - Subperiosteal
 - Periosteal
- **According to duration and severity**
 - **Acute**—it occurs initial infection with the microorganism
 - **Chronic**—it can be primary or secondary
 - **Primary**—virulence of the microorganism is low and the host resistance is high. This type is not preceded by an episode of acute symptoms.
 - **Secondary**—it is secondary to incompletely treated acute osteomyelitis.
- **Depending upon the presence or absence of suppuration**
 - **Suppurative:**
 - Acute suppurative osteomyelitis
 - Chronic suppurative osteomyelitis
 - Infantile osteomyelitis
 - **Nonsuppurative:**
 - Chronic nonsuppurative
 - Focal sclerosing
 - Diffuse sclerosing

- *Radiation osteomyelitis*
- *Garre's sclerosing osteomyelitis*
- *Osteomyelitis due to specific infection:*
 - Actinomycosis
 - Tuberculosis
 - Syphilis.

Clinical Staging of Osteomyelitis

- *Initial stage*—spontaneous pain (localized).
- *Acute stage (suppurative stage)*—in this stage, there is severe pain, soreness and looseness of the involved teeth.
 - *Early acute stage*—in reference of to the involved tooth, progressive sensitivity of the adjacent teeth to percussion and pain in the involved side of jaw.
 - *Late acute stage*—paresthesia or anesthesia of the lip region supplied by the mental nerve. Other systemic symptoms can occur.
- *Osteonecrotic stage*—diminished spontaneous pain, abscess formation and pus discharge (**Fig. 19-28**).
- *Sequestrum stage*—lack of symptoms sequestrum formation visible on the radiograph.

Fig. 19-28: Osteomyelitis in osteonecrotic stage showing extraoral discharging sinus.

Occurrence

- *Sex*—it is more common in men, than women.
- *Sites*—it occurs in mandible in premolar area because:
 - The cortical plate of the bone in time mandible is dense. It takes longer time for sinus formation and release of pits and hence, the infection gets directs into spongiosa and spreads.
 - Removal of posterior mandibular teeth is attended by more damage to the bone.
 - Mandible is less vascular than maxilla.
 - Thin cortical plates and relative paucity of medullary tissue in the maxilla precludes confinement of infection within the bone and permits dissipation of edema and pus into the soft tissues and paranasal sinuses.
- *Infantile osteomyelitis* is more common in maxilla than mandible, as it spreads by hematogenous route and maxilla has more blood supply than mandible.

Clinical Features

Acute

- *Initial symptoms*—it has rapid onset and course. Patient complaint of severe pain, paresthesia or anesthesia of the mental nerve.
- *Initial signs*—at this stage, the process is truly intra-medullary, therefore swelling is absent, teeth are not mobile and fistulae are not present.
- *Late symptoms*—there is deep intense pain, anorexia, malaise, fever, and regional lymphadenopathy. Patient also complain of soreness of involved teeth which become loose within 10 to 14 days. There is also fetid oral odor.
- *Late signs*—pus exudates around the gingival sulcus or through mucosal and cutaneous fistula. There is firm cellulitis of cheek and abscess formation with localized warmth and tenderness on palpation. The patient feels toxic and dehydrated.

Chronic

- *Onset*—it has insidious onset with slight pain, slow increase in jaw size and a gradual development of sequestra without fistula.
- *Symptoms*—it is painless unless there is an acute or sub-acute exacerbation.
- *Necrotic bone*—in some cases, necrotic bone may be visible inside the oral cavity (**Figs 19-29A and B**).
- *Sinus*—intraorally and extraorally sinus develops (**Figs 19-30A and B**) intermittently and drains small amount of pus and then gradually heals. Sinus extends from medullary bone, through cortical plate, to mucous membrane or skin. Sinus may be at a considerable distance from the offending infection.
- *Signs*—local tenderness and swelling develop over the bone in the area of abscess (**Fig. 19-31**).
- *Lymph nodes*—regional lymphadenopathy is present.

Radiographic Features

Acute

- *Radiodensity*—about 10 days after acute infection, the density of trabeculae will be decreased, with blurred and fuzzy. For the radiographs to reveal any changes, there must be a loss of from 30 to 60% in the calcium content.
- *Trabecular pattern*—the earliest radiographic change is that trabeculae in the involved area are thin, of poor density and slightly unsharp or blurred. The trabeculae soon lose their continuity as well as the little density present. Individual trabeculae become fuzzy and indistinct.

Figs 19-29A and B: Necrotic bone seen in osteomyelitis.

- *Multiple radiolucency*—subsequently, multiple radiolucencies appear which become apparent on radiograph. These are enlarged trabeculae spaces caused by foci of necrosis and frank bone destruction.
- *Saucer shaped destruction*—in some cases, there is a saucer shaped area of destruction with irregular margins and containing teeth, with variable amount of supporting bone.
- *Periosteal reaction*—it can either stimulate bone resorption or bone formation. Inflammatory exudate can lift the periosteum and stimulates bone formation. Radiologically, it appears as a thin faint, radiopaque line, adjacent to and almost parallel or slightly convex to the surface of the bone.
- *Lamina dura*—there is loss of continuity of lamina dura, which is seen in more than one tooth.
- *Technetium bone scan followed by gallium citrate scan*—it will help to confirm the diagnosis. With inflammatory lesion, a positive result on the Tc^{99} scan indicates increased bone activity and a positive result on gallium scan in the same location indicates an inflammatory reaction.

Figs 19-30 A and B: Extraoral discharging sinus seen in osteomyelitis (Courtesy Dr Bande).

Fig. 19-31: Swelling seen in alveolar bone in case of osteomyelitis of mandible (Courtesy Dr Bande).

- *Osteomyelitis in children*—it shows paucity or absence of trabeculae in the tooth bearing area. In some cases, there may be loss of density on a part or whole of the cortical layer of one or more tooth follicles. Follicular cortex may become fragmented or lost over the variable area. Following destruction of the wall of the tooth follicle, it is common for the teeth to show evidence of moving.

Chronic

- *Radiodensity*—single or multiple radiolucencies of variable sizes are seen.
- *Margins*—irregular outline and poorly defined borders.
- *'Moth eaten appearances'* is seen as the radiolucent areas enlarge and become irregular in outline and get separated by islands of normal appearing bone. This is due to the enlargement of medullary spaces and widening of Volkmann's canals, secondary to lysis of bone and replacement with granulation tissue.
- *Sequestra*—segments of necrotic bone become detached; irregular calcified areas separate from the remaining bone and become distinguishable as sequestra. Sequestra are more dense and better defined (**Figs 19-32A and B**) due to following reasons:
 - Sclerosis that was induced before the bone became necrotic.
- Dead bone has affinity for calcium. Hence, it absorbs calcium.
- Inflammatory reaction is the probable stimulation for demineralization of the vital bone surrounding the sequestra. This enhances the contrast.
- *Teeth*—the roots of the teeth may undergo external resorption and the lamina dura may become less apparent as it blends with surrounding granular sclerotic bone.
- *Fistula tract*—fistula tracts may appear on the radiograph as radiolucent bands transversing the body of the jaw and penetrating the cortical plates.
- *Joint involvement*—in patients with extensive chronic osteomyelitis, the disease may spread to mandibular condyle and joint, resulting in septic arthritis.
- *Computed tomography*—computed tomography is more useful in revealing the internal structure and sequestra more readily than conventional radiography (**Figs 19-33 and 19-34**).

Figs 19-32A and B: Sequestration seen as horizontal radiopaque structure in the mandibular bone.

Figs 19-33A and B: Computed tomography showing destruction of mandibular cortex.

Fig. 19-34: Three dimensional CT of osteomyelitis.

- *Pathological fracture*—in some cases osteomyelitis can lead to pathological fracture (Fig. 19-35).

Fig. 19-35: Osteomyelitis with pathological fracture.

Diagnosis

- *Clinical diagnosis*—pain, swelling, fever is present.
- *Radiological diagnosis*—loss of lamina dura, saucer shaped destruction, sequestrum formation and moth eaten appearance will give clue to the diagnosis.
- *Laboratory diagnosis*—the medullary spaces are filled with inflammatory exudate that may or may not progress to the actual formation of pus. The inflammatory cells are chiefly neutrophilic polymorphonuclear leukocytes, but may show occasional lymphocytes and plasma cells.
- *Investigation to be carried out in osteomyelitis*—investigation like gram staining, culture and sensitivity, WBC count and complete hemogram, blood sugar, Mantoux test, radiographs, scintigraphy and computerized tomography.

Differential Diagnosis

- *Paget's disease*—it affects multiple bones and the complete involvement of individual bone.

- *Eosinophilic granuloma*—margins are better than osteomyelitis and have no evidence of bone sclerosis.
- *Difference between carcinoma and osteomyelitis.*

Features	Osteomyelitis	Carcinoma
Age	Usually under 40 years	Post middle age
Progression	Fast	Slower
Extent of involvement	Large involvement and sporadic occurrences	Relatively continuous destruction
Sequestrum	Yes	None
Osteosclerotic formation	Yes	None
Periosteal formation	Large area involved mainly in the parallel direction	Generally none except in some sarcoma
Residual small bony fragment	None	Formation seen within the lesion
Bone scintigram	Negative uptake at the sequestration	Strong positive uptake seen

Management

The goal of definitive therapy is to attenuate and eradicate the proliferating pathogenic microorganisms and to support healing. This is accomplished by removing pathogenic suppurative debris, providing regional stability and disrupting pathophysiology barriers while re-establishing vascular permeability to the infected area.

- *Incision and drainage*—when early diagnosis is made, drainage of the fluctuant areas should be carried out under antibiotic cover. After pus is evacuated, drains are placed. The consistency, color and odor of the pus may provide important clues to the diagnosis and initial treatment.
- *Irrigation and debridement of necrotic areas*—thorough debridement of the affected areas should be carried out. Debride any foreign bodies, necrotic tissue or sequestra. These areas may be irrigated with hydrogen peroxide and saline.
- *Empiric therapy:*
 - *Regimen I*—aqueous penicillin 2 million units, IV, 4 hourly plus oxacillin 1 gm, IV, 4 hourly.
 - *Regimen II*—if the patient is asymptomatic after 48 to 72 hours, then penicillin V 500 mg, 6 hourly and dicloxacillin 250 mg, 4 hourly, for an additional 2 to 4 weeks.
- *Definitive therapy*—culture and sensitivity testing is performed, and the antibiotic therapy is then modified accordingly, particularly if the infection appears to be refractory after the treatment is instituted. If favorable response occurs, no change is indicated.

- *Initial therapy with gram stain result*—if the stain shows predominance of gram -ve cocci in clumps suggestive of staphylococcus, penicillinase resistant penicillin alone is advised.
 - An initial course of oxacillin 1gm IV after every 4 hours.
 - If improvement occurs then orally dicloxacillin 250 mg after every 4 hours should be administered.
- If the stained slide shows predominately gram +ve rods, then an established working diagnosis of anaerobic infection (bacteroides) is made.
 - An aqueous penicillin 2 million units may be given IV, after every 4 hours.
 - An oral antibiotic like penicillin V may be started after 48 to 72 hours.
- *If patient is allergic to penicillin:*
 - *Clindamycin* is recommended. In acute phase 600 mg, after every 6 hours should be given. Once the acute phase is over, orally 450 mg may be given, after every 4 hours.
 - *Cephalosporin* or cefazolin is the third drug of choice in case of allergy to penicillin. Cefazolin 500 mg, IV / IM, after every 8 hours. Once acute symptoms have subsided, cephalexin 500 mg, after every 6 hours is recommended.
 - As a fourth choice *erythromycin* is also useful 2 gm IV after every 6 hours. When acute stage is resolved then 500 mg is given orally, after every 6 hours.
- *Other modalities*—intra-arterial antibiotic therapy and local implantation of antibiotics. Another unique pharmacological treatment is the use of prostaglandin inhibiting salicylates therapy, in an attempt to diminish osteolytic destruction in osteomyelitis model.
- *Extraction*—extraction of carious teeth with periapical infection, should be done. It should be carried out to remove the source of infection from the oral cavity.
- *Supportive therapy:*
 - *Adequate rehydration*—patients is suffering from osteomyelitis required adequate rehydration in the form of fluids.
 - *Rich nutritional diet*—rich nutritional diet should be given.
 - *Vitamin therapy*—multivitamin supplements should be given.
- *Sequestrectomy*—it is the removal of sequestra which are small pieces of necrotic bone that are avascular and harbor microorganisms. Sequestra are not generally seen until two weeks after initiation of the infection. They get resorbed or get spontaneously expelled out from the mucosal or skin surface. If sequestra are not removed, they get chronically infected and also infect the surrounding tissues. This will lead to further sequestration and bone loss. Hence, sequestra need to be removed.
- *Saucerization*—it means excision of the margins of necrotic bone. This will results in better visualization of sequestra and excision of margins of the affected bone. In chronic osteomyelitis, it allows removal of formed and forming sequestra. This usually performed under local anesthesia by raising buccal flap. All the granulation tissue, along with loose bony fragments, is removed from the bony bed using curette and the area is thoroughly irrigated.
- *Closed wound irrigation and suction*—after intraoral sequestrectomy and saucerization, small pediatric nasogastric feeding tubes are used. Drains are placed through separate skin incisions along the decorticated surface and affixed to each other and to the bone with catgut sutures, through the holes drilled in the bone. After tube placement, water tight closure of the wound is achieved and the tubes are flushed with saline. The irrigating solution is flushed through one tube and the other tube is connected to low pressure suction. Various irrigating solutions may be employed, which often contain antibiotics, wetting agents and proteolytic enzymes. Systemic antibiotics should be continued throughout the period of irrigation.
- *Decortication*—decortication of mandible refers to removal of the chronically infected and inferior cortical plates, 1-2 cm beyond the area of involvement. Thus, access is provided to the medullary cavity. Decortication should be performed in sub-acute and chronic stages. It is based on the principle that the involved cortical bone is avascular and harbors microorganisms, while an abscess exists within the medullary cavity where antibiotics can not penetrate. This should be performed where initial conservative regimens have failed.
- *Resection and immediate reconstruction*—resection of the region of osteomyelitis with immediate reconstruction is controversial. Osteotomy is performed in the bleeding bone by intraoral route. Resection is indicated when antibiotics combined with decortication fail to cure the condition in patient where involucrum formation is inadequate, no involucrum in formed after months of antibiotics therapy, the lingual and buccal plates of the mandible are extensively destroyed and considerable destruction of the mandibular ramus occurs without new bone formation. Immediate reconstruction offers the obvious advantage of shortening the period of illness and seeding of rehabilitation.
- *Hyperbaric oxygen therapy*—the scientific foundation for oxygen therapy was laid down in 1960. It was first used in the treatment of gas gangrene. Over the last few decades, hyperbaric oxygen therapy has emerged as a potent alternative to surgical reperfusion and as an adjunctive to host response. HBO therapy has specific applications in oral and maxillofacial surgery; it is used

in the prevention and adjunctive treatment of osteomyelitis, osteoradionecrosis and certain soft tissue infections. The partial pressure of oxygen in osteomyelitis bone is significantly decreased, compared with normal bone. The oxygen tension of normal bone is between 40 to 45 mm of Hg. The oxygen tension in osteomyelitis bone involves a combination of factor, but its oxygen tension in osteomyelitis bone varies from 10-20 mm of Hg. In osteomyelitis, bone has increased consumption of oxygen may be because of greater inflammatory response, cellular exudation and respiration of phagocytes. Secondary to infection, infective organisms also consume more oxygen.

- **Rationale behind oxygen therapy**—adequate tissue oxygen is necessary for fibroblast proliferation. Fibroblast lay down collagen, which provides a framework for capillary formation. The most important aspect of HBO is its positive enhancement of neoangiogenesis in the aerobic portion of the proliferative phase of wound healing. Under the influence of hyperbaric oxygen therapy, endothelial proliferation is seen, which obliterates avascular and ischemic pieces. Free oxygen radical is formed during hyperbaric oxygen therapy that is toxic to many pathogenic anaerobes. HBO is bactericidal for many anaerobic microorganisms. Besides these, the endotoxin liberated by pathophysiological activity of microorganisms is rendered inert by exposure to elevated partial pressure of oxygen. HBO enhances lysosomal degradation potential, by enhancing the development of intracellular halides in leukocytes and oxygen radicals, which are a major component of catabolic enzymes of the macrophage lysosomes. Formation of this enzyme is depressed or decreased in hypoxic environment, such as that found in osteomyelitis foci. Thus, leukocytic bactericidal ability is enhanced. Patient usually experiences relief from pain within 3 to 5 sittings treatment of with rapid closure of draining fistulae. Sequestra get localized and there is rapid progression to osseous reconsolidation and fibrous union.
- **Procedure**—scrubbing the exposed bone with antiseptic solution such as acriminoacridine. Purulent wound should be covered with neomycin dressing. An antibiotic, preferably penicillin, erythromycin or tetracycline, is administered orally. Vitamin E is also given (100 gm) daily to decrease oxygen seizure susceptibility. Patient is placed in multiplace/monoplace chamber and a concentration of 100% O₂ is given. Duration of treatment is of 1.5 to 2 hours for 5 to 6 days in a week, for a total of 60 treatments. Daily wound irrigation and debridement are often required. After 6 months ten additional 2 hour

treatments are advised, followed by ten treatments annually thereafter.

- **Contraindication**—hyperbaric oxygen therapy should not be given in pneumothorax, asthma, COAD, optic neuritis, acute viral infection, URI, congenital spherocytosis, and pregnancy.
- **Complication**—complication of hyperbaric oxygen therapy includes decompression sickness, eustachian tube dysfunction, high pressure nervous syndrome and pneumothorax.

Different Types of Osteomyelitis

Infantile Osteomyelitis

It is a rare type of osteomyelitis seen in infants few weeks after the birth. It usually involves the maxilla.

Route of infection

- **Hematogenous route**—infantile osteomyelitis is usually transferred through the hematogenous route.
- **Trauma**—prenatal trauma of oral mucosa from obstetrician's finger.
- **Infection**—infection from mucous bulb are used to clear the airway immediately after birth.
- **Infected nipple**—infected human or artificial nipple.

Clinical features

- **Sites**—it is more common in maxilla due to hematogenous route. The infection is thought to arise in maxillary antrum or lacrimal sac. It appears to center in the region of first deciduous molars and the adjacent portion of maxilla, although it may involve the inferior aspect of the orbit.
- **Symptoms**—there is fever, anorexia and dehydration. In some cases, convulsions and vomiting may occur.
- **Signs**—redness and edema of eyelids, alveolar bone and palate of the affected side. Intracanthal swelling, palpebral edema, conjunctivitis and proptosis may result. Maxilla on affected side is swollen both buccally and palatally, especially in the molar region.
- **Sinus**—sinus develops and discharges pus intraorally and extraorally.
- **Complication**—complications may occur like TMJ infection and devitalization of adjacent tooth germs may occur.

Radiographic features

- *It will be same as in acute osteomyelitis.*

Diagnosis

- **Clinical diagnosis**—sinus, fever, pain with maxillary involvement in the infant will give clue to the diagnosis.

Management

It is same as that for acute osteomyelitis.

Diffuse Sclerosing Osteomyelitis

In this type, there is reactive proliferation of bone to infectious process occurs. It occurs due to low grade infection. In this, chronic bacterial infection of bone creates smoldering mass of chronically inflamed tissue which initiates sclerosis of surrounding bone.

Clinical features

- *Age and sex*—it can occur at any age but most common in older persons. Most cases are reported in blacks and in female.
- *Sites*—it is common especially in edentulous mandibular jaw.
- *Symptoms*—symptoms are very mild to absent. During the period of growth, the patient complains of pain and tenderness. Pain persists for few weeks to months to even years.
- *Signs*—jaws may be slightly enlarged on the affected side.

Radiographic features

- *Location*—usually large portions of mandible are involved. Surface of new bone is usually smooth.
- *Radiodensity*—there is presence of osteolytic and osteosclerotic zones. As the lesion progresses, there is increase in the size of the involved part.
- *Margins*—margins are ill defined.
- *Granular densification*—stripped or granular densification of bone, caused by subperiosteal deposition of new bone, obscures the intrinsic bone structure or deposition of new bone on the surface of marrow spaces. The deposition is more on the buccal and inferior surface of the jaw.
- *Tooth root*—there is shortening of tooth root.
- *Scintigraphy*—scintigraphy shows uptake of ^{99m}Tc polyphosphate in diseased area, suggesting active bone deposition.

Diagnosis

- *Clinical diagnosis*—as symptoms of this disease are mild, it is not possible to make confirm clinical diagnosis.
- *Radiological diagnosis*—there is granular densification, osteolytic and osteoblastic zone. Scintigraphy will show active bone deposition.
- *Laboratory diagnosis*—there is increased ESR. Biopsy shows bone in 'mosaic' pattern, indicative of repeated periods of resorption followed by repair. The soft tissue between the individual trabeculae is fibrous and show proliferative fibroblasts and occasional small capillaries focal collections of lymphocytes and plasma cells.

Management

- *Infection control*—the best management method for diffuse sclerosing osteomyelitis is resolution of active foci of

infection in the oral cavity. This can be done by extraction of teeth, periodontal management.

- *Management of secondary osteomyelitis*—in some patient, secondary osteomyelitis may develop. It is managed same as that acute and chronic osteomyelitis.

Condensing Osteitis or Focal Sclerosing Osteomyelitis

If the exudate is of low toxicity and long standing then the resulting mild irritation may lead to circumscribed proliferation of periapical bone, appearing as condensing osteitis or focal sclerosing osteomyelitis. There is deposition of new bone along the existing trabeculae, a process known as appositional bone deposition.

Clinical features

- *Age*—it occurs almost in young person, before the age of 20 years.
- *Location*—the tooth commonly affected is mandibular first molar with a large carious lesion. It is associated with non-vital teeth or in teeth undergoing the process of degeneration.
- *Symptoms*—tooth is usually asymptomatic. But in some cases, patient may report pain or tenderness on percussion or palpation.

Radiographic features

- *Appearance*—it appears as localized area of radiopacity surrounding the affected tooth, which may extend below the apex (Fig. 19-36).
- *Margins*—it may be variable in size and extent, with margins from well defined to very diffuse. At the diffused margins, the thickened trabeculae can be seen in continuation of adjacent normal bone (Figs 19-37A and B).
- *Alveolar bone*—the alveolar bone may be sclerose between two adjacent teeth, extending to the crest without any evidence of periodontal disease.

Fig. 19-36: Condensing osteitis seen at the apex of the tooth.

Figs 19-37A and B: Condensing osteitis showing radiopacity at the apex of tooth (Courtesy Dr Ashok).

- *Inferior dental canal*—due to sclerosis, inferior dental canal may be narrowed.
- *Bone scar*—this is the residual area of condensing osteitis after resolution of infection.

Diagnosis

- *Clinical diagnosis*—it is not possible to make clinical diagnosis.
- *Radiological diagnosis*—localized uniform zone of increase radiodensity at the apex of tooth will be diagnosed this condition.
- *Laboratory diagnosis*—it appears as an area of dense bone with trabeculae borders lined by osteoblasts. Chronic inflammatory cells, plasma cells and lymphocytes are seen in the scanty bone marrow.

Differential diagnosis

- *Hypercementosis*—it forms an integral part of the malformed root within intact lamina dura and periodontal ligament space, in contrast to condensing osteitis which is outside the lamina dura and periodontal ligament space.

- *Periapical cemental dysplasia*—it occurs in association with vital tooth and is surrounded by radiolucent halo. Condensing osteitis is not well defined.
- *Osteosclerosis*—it occurs in edentulous area and is associated with vital teeth.
- *Projected radiopacities*—it can be differentiated by 'slob' technique.
- *Enostosis*—it is a small area of greater density that is present in many bones. But in cases of enostosis, more than one are present in the jaws and margins are usually sharp. If the mass is separated from the adjacent tooth by more than couple of millimeters of normal bone, it is enostosis.
- *Odontome*—it has got small radiolucent foci within the dense radiopaque area.
- *Paget's disease*—the adjacent bone also show evidence of altered structure.
- *Torus mandibularis*—the site, bilateral nature and symmetry favors the diagnosis of *torus mandibularis*.
- *Foreign bodies*—there is a related history; the shape and density varies.

Management

- *Endodontic treatment*—endodontic treatment should be carried out with affected tooth. This will resolve the lesion.
- *Extraction*—if the tooth is unrestorable extraction of tooth should be carried out.

Osteomyelitis with Proliferative Periostitis (Garre's Osteomyelitis)

It is also called as '*Osteomyelitis with proliferative periostitis; Periostitis ossificans*'. It was first described by Carl Garre in 1893. But the use of term Garre's osteomyelitis is controversial. The reason for this is that when Garre's discovered it X-ray are not discovered. So the word periostitis does not arise at that time.

It is characterized by formation of hard bony swelling at the periphery of the jaw. It is essentially a periosteal osteosclerosis analogous to the endosteal sclerosis of chronic, focal and diffuse sclerosing osteomyelitis.

For the lesion to develop following conditions should be satisfied.

- The periosteum must possess high potential for osteoblastic activity.
- Mild infection serves as a stimulus.
- Fine balance should be maintained between the resistance of host and number and virulence of organisms.

Clinical features

- *Age and sex*—occurs mainly below 30 years; males are affected more commonly than females.

- **Sites**—most frequently involve the anterior surface of tibia and femur. Mandible is affected more commonly than maxilla. It commonly occurs at the inferior border of mandible, in first molar region.
- **Appearance**—it is presented as hard non-tender swelling with medial and lateral expansion of jaw.
- **Size**—mass varies in size from 1 or 2 cm to the involvement of the entire length on the affected side. Cortex may become 2 to 3 cm thick.
- **Signs**—it may become secondarily infected and cause considerable discomfort.
- **Other findings**—lymphadenopathy, hyperpyrexia and leukocytosis are common findings.

Radiographic features

- **Carious tooth**—intraoral radiograph will reveal a carious tooth opposite the hard bony mass.
- **Cortex**—shadow of thin convex shell of bone over the cortex may be seen. No trabecular pattern between shell of new bone and cortex.
- **Onion skin appearance**—as infection persists, the cortex thickens and becomes laminated (**Fig. 19-38**) with alternating radiopaque and radiolucent layers (*onion skin appearances*).
- **Cancellous bone**—adjacent cancellous bone may remain normal, become sclerotic or show some areas of osteolytic changes within the scleroses spongiosa.
- **Small sequestra**—within the new bone osteolytic radiolucencies or small sequestra are present.
- **Computed tomography**—it is superior to conventional radiography.

Fig. 19-38: Proliferative osteomyelitis showing radiopacity at the apex which is having laminar structure.

Diagnosis

- **Clinical diagnosis**—it is not possible to make clinical diagnosis.

- **Radiological diagnosis**—'onion peel appearance' is seen as lamination parallel to cortex.
- **Laboratory diagnosis**—biopsy shows reactive new bone and osteoid tissue, with osteoblasts bordering many of the trabeculae. These trabeculae often are oriented perpendicular to the cortex, with the trabeculae arranged parallel to each other or show a retiform pattern.

Differential diagnosis

- **Ewing's sarcoma**—Bony enlargement caused by sarcoma develops more rapidly. Sun ray appearance is classical. Facial neuralgia and lip paresthesia are frequent complications of this entity.
- **Caffey's disease** (infantile cortical hyperostosis)—It is found at the angle or ramus of the mandible and presents before 2 years as compared to Garre's osteomyelitis which is found in posterior tooth bearing areas with later onset. Caffey's disease is developed in more than one bone, as compared to Garre's osteomyelitis, which is developed in one bone.
- **Fibrous dysplasia**—it is not associated with dental infection and is likely to be found in maxilla. In Garre's osteomyelitis, there is thickened cortex, as compared to fibrous dysplasia in which there is a thin cortex. Density of fibrous dysplasia is much more uniform than in Garre's osteomyelitis, which may be mottled with alternating areas of sclerosis and osteolysis.
- **Osteosarcoma**—sunray appearance is seen.
- **Ossifying sub-periosteal hematoma**—it will not be so uniformly radiopaque, having either more mottled appearances or even trabeculated pattern. History of trauma is present.
- **Peripheral osteoma, tori, exostosis**—they appear as dense uniform radiopaque masses on the jaw or protruding from the cortex.
- **Infantile cortical hyperostosis**—generalized expansion of cortices of several bones.

Management

- **Endodontic therapy**—this should be carried out in the tooth.
- **Extraction**—if the tooth is unrestorable then extraction should be carried out.

Actinomycotic Osteomyelitis

Actinomycosis is a chronic infection manifesting, both, granulomatous and suppurative features, that usually involve the soft tissues and occasionally the bone of cervicofacial, abdominal and thoracic region. About 1/3rd of the cases are cervicofacial.

Patient presents with soft tissue masses of skin, which have purplish, dark red, oily areas with occasional zone of fluctuance. Actinomycosis produce *lumpy jaw*—actinomycosis infection produces dense bone and scarring

of soft tissues and has been described as 'lumpy jaw'. Actinomycosis will result in osteomyelitis of jaw bone. It is common in cattle and rare in human being. Soft tissues provide a harbor for organisms and reduce the blood supply to the affected region.

Tuberculous Osteomyelitis (Fig. 19-39)

Bone and joint tuberculosis is always hematogenous in origin. Primary focus is related to lung when disease is acquired by inhalation of human strain or to gastrointestinal tract if it is acquired by ingestion of bovine tubercle. The disease starts within the synovial membrane or in intra-articular bone. The disease may develop in synovial joints especially the knee and hip joint. Tuberculous osteomyelitis of maxilla or mandible or TMJ are rare entities.

Fig. 19-39: Moth eaten type of appearance seen in mandible due to osteomyelitis with history of tuberculosis in this patient.

Radiation Osteomyelitis

It is an infection of the irradiated bone. It occurs after exposure to radiation (40 to 80 Gy), bone undergoes marked decreased in vascularity. Such bone has poor defensive process and is susceptible to traumatic injury. It draws infection from extraction wound and infected pulp, severe periodontitis and denture stomatitis. It will cause death of bone cells and result in progressive obliterative arteritis. This results in aseptic necrosis of the portion of bone directly in beam of radiation, with compromised vascularity in the adjacent bone.

Pathogenic organisms are introduced into this irradiated bone through odontogenic infections, compound fractures of the jaws and mucosal lacerations. The organisms most commonly found are *Staphylococcus aureus*, *Staphylococcus epidermidis*. Higher incidences in jaw are necrotic due to higher degree of infections and frequent trauma to which these bones.

Osteomyelitis can occur in irradiated jaw. Intense pain and facial fistula develop from the subperiosteal tissues. Spread is diffuse and throughout with signs of inflammation and swelling.

Chronic Tendoperiostitis

It is reactive hyperplasia of bone that is exacerbated by overuse of the masticatory muscle. It is caused by parafunctional habits like bruxism, clenching, nail biting. Masseter inhibitory reflexes were abnormal in this case.

Clinical Features

- *Age and sex distribution*—it is commonly seen in 4th decade of life without sex predilection.
- *Site*—it is more common in masseter and digastric muscle.
- *Symptoms*—recurrent pain, swelling of cheek, trismus, triad of symptoms.
- *Signs*—there is as such no suppuration is present.

Radiological Features

- *Location*—it is seen in anterior region of mandibular angle and posterior region of mandibular body.
- *Sclerosis*—sclerosis is limited to the one quadrant only. There is radiolucent zone inside the radiopacity.
- *Erosion*—erosion of inferior border of mandible can be present.

Diagnosis

- *Clinical diagnosis*—triad of symptoms of cheek swelling, trismus and recurrent pain will give clue to the diagnosis.
- *Radiological diagnosis*—sclerosis at angle of mandible with radiolucent zone in it is present.
- *Laboratory diagnosis*—biopsy show reactive bone, dense bone with few foci of inflammation.

Management

- *Muscular relaxation method*—this is carried out by rotational exercise, myofeedback, soft diet should be given.
- *Muscle relaxant drugs*—muscle relaxant drugs like diazepam, meprobamate should be given.
- *Occlusal splint*—occlusal splint should be given to the patient to control parafunctional habits.

SAPHO Syndrome

SPAHO syndrome includes Synovitis, Acne, Pustulosis, Hyperostosis, and Osteitis. It occurs due to unknown cause. Genetic predisposition is present in this case.

Clinical Features

- *Age and sex distribution*—patient affected in the age group of 50 to 60 years.

- *Site*—most commonly involve site are anterior chest wall, clavicle, and ribs.
- *Skin lesion*—palmoplantar pustulosis, pustular psoriasis, and acne is present.

Radiological Features

- *Appearance*—osteolytic areas are scattered in the randomly in the sclerotic bone.
- *Periosteal bone reaction*—it is present in many cases. There is no perforation of bone.
- *External bone resorption*—external bone resorption of mandible is common in this condition.
- *Scintigraphy*—it will show involvement of multiple site of bone deposition.

Diagnosis

- *Clinical diagnosis*—it is easy to make clinical diagnosis by 5 typical features of this syndrome.
- *Radiological diagnosis*—periosteal bone reaction with multiple sites of bone deposition.
- *Laboratory diagnosis*—biopsy shows bone remodelling, there is also interconnecting trabeculae of vital reactive mixed with fibrous connective tissue.

Management

- *Steroidal and non-steroidal anti-inflammatory drugs*—these are most effective agents to relieve the symptoms.
- *Decortication*—this is effective in some cases of SPAHO syndrome.

Facial Space Infections

Facial spaces are potential spaces situated between the planes of fascia, which form natural pathways along which the infection may spread.

- *Primary*—these are directly related to teeth:
 - *Maxillary spaces*—it includes canine space, buccal space, infratemporal space and parotid space.
 - *Mandibular spaces*—it includes space for body of mandible, submental space, sublingual space, submandibular space, buccal space and pterygomandibular space.
- *Secondary*—these are not directly related to teeth involved maxillary spaces. It includes:
 - Masseteric
 - Pterygomandibular
 - Superficial and deep temporal
 - Lateral pharyngeal
 - Retropharyngeal
 - Prevertebral.

Based on Clinical Significance

- *Face*—buccal, canine, masticatory, parotid.
- *Suprahyoid*—sublingual, submandibular, pharyngo-maxillary, peritonsillar.
- *Infrahyoid*—anterovisceral (pretracheal)
- *Space of total neck*—retropharyngeal, space of carotid sheath.

Different types of space infection is discussed below:

Canine Space

Anatomy

- *Location*—one of the potential spaces that is frequently the seat of infection is the canine fossa. This space actually lies between the anterior surface of the maxilla and the overlying elevator muscle of upper lip.
- *Content*—the fossa contains considerable amount of connective tissues and fat, which allow the accumulation of tissue fluid and pus.
- *Boundaries*—it is bounded by:
 - *Superiorly*—by levator labii superioris alequae nasi.
 - *Anteriorly*—by orbicularis oris.
 - *Posteriorly*—by buccinator.

Clinical Features

- *Location of swelling*—swelling just lateral to the nose, obliterating the nasolabial fold. In some cases canine space infection may extend to orbit (**Fig. 19-40**).
- *Intraoral location*—intraorally, swelling is present in the labial sulcus. Rarely, palatal swelling is encountered.

Fig. 19-40: Canine space infection extending to the orbit.

Buccal Space

Anatomy

- **Location**—this space is situated between the buccinator and masseter muscle. It lies superficial to the buccinator muscle and buccopharyngeal space.
- **Contents of space**—it contains buccal pad of fat, Stensen's duct, anterior facial artery and transverse facial artery and vein.
- **Boundaries**—it is bounded by:
 - *Medially*—by buccinator muscle and buccopharyngeal fascia.
 - *Laterally*—by skin of cheek.
 - *Anteriorly*—by zygomatic arch and depressor muscle of corners of mouth.
 - *Superiorly*—by zygomatic arch.
 - *Inferiorly*—by lower border of mandible.
 - *Posteriorly*—by masseter muscle and pterygomandibular raphe.

Clinical Features

- **Location of swelling**—swelling extent from lower border of mandible to level of zygomatic arch (**Fig. 19-41**). Swelling arises due to infection from mandibular or maxillary molar or premolar, if apex is above the attachment.
- **Symptoms**—facial swelling with little trismus.
- **Sign**—swelling is dome shaped and in some cases periorbital edema develops.

Fig. 19-41: Buccal space infection showing dome shape swelling.

Parotid Space

Anatomy

- **Content**—it is a compartment formed by splitting of investing layer of deep cervical fascia. It contains parotid gland as well as extra-glandular and intra-glandular

parotid lymph nodes. It also contains external carotid, internal maxillary and superficial temporal artery.

- **Attachment of gland**—the gland is itself attached strongly to the facial covering and there is very little intervening connective tissue. This makes extension of infection into parotid space very difficult.

Origin of Infection

- **Blood born infection**—most of the infections are blood borne or occur as retrograde infection through the parotid duct.
- **Retrograde extension**—it reaches from the lateral pharyngeal space or by retrograde extension along the parotid gland.
- **May break into lateral pharyngeal space**—primary infections of parotid space break into lateral pharyngeal space readily because the fascia is thin over the deep portion of the parotid space.

Clinical Features

- **Location of swelling**—the swelling extends from the level of the zygomatic arch to the lower border of the mandible. Posteriorly, it extends into the retromandibular region and anteriorly, it ends at the end of the anterior border of ramus.
- **Signs**—the swelling tends to evert the lobule of ear.
- **Symptoms**—the patient complains of pain, which is referred to the ear and accentuated on eating.
- **Diagnosis**—diagnosis is made by following features:
 - Eversion of lobule of ear (**Fig. 19-42**).
 - No evidence of trismus.
 - Possible escape of pus from parotid duct, when the gland is milked.
 - All signs of abscess formation.

Fig. 19-42: Parotid space infection showing eversion of ear lobule.

Infratemporal Space

Anatomy

- **Location**—it is an irregularly shaped space which lies behind the posterior surface of the maxilla.
- **Contents of space**—it contains pterygoid plexus, internal maxillary artery, the mandibular, mylohyoid, lingual, buccinator and *chorda tympani* nerves and external pterygoid muscle.
- **Boundaries**—it is bounded by:
 - **Laterally**—by tendon of the temporal muscle, coronoid process and ramus of mandible.
 - **Medially**—by lateral plate of pterygoid process, inferior belly of the lateral pterygoid muscle and lateral wall of pharynx.
 - **Posteriorly**—by lateral pterygoid muscle, condyle, temporal muscle and the fossa is limited by parotid gland, which overlaps into it.
 - **Anteriorly**—it is limited by maxillary tuberosity.
 - **Superiorly**—the roof of infra-temporal fossa is formed by greater wing of sphenoid.
 - **Inferiorly**—it communicates with pterygomandibular space.

Spread

- **Spread to cavernous sinus**—infra-temporal infection can extend via the plexus of veins, through the inferior orbital fissure into the terminal part of inferior ophthalmic vein and then, through the superior orbital fissure into cavernous sinus.
- **Spread to pterygomandibular space**—the infection from this space can extend into pterygomandibular space.

Clinical Features

- **Location**—extraoral swelling over the region of sigmoid notch and TMJ joint area and intraorally swelling is usually in the tuberosity area.
- **Symptoms**—the patient may exhibit trismus and sometimes swelling of eyelids, if there is involvement of post-zygomatic fossa.
- **Signs**—entire cheek may be swollen, if the buccal space is also involved.
- **Pharynx involvement**—the involvement of pharynx may cause dysphagia and severe pain or a feeling of pressure in the general area of infection.

Space for the Body of Mandible

Anatomy

- **Location**—it is formed as the external cervical fascia splits medially and laterally, at the inferior border of the mandible and becomes continuous superiorly with alveolar mucoperiosteum.

- **Content**—it contains the mandible anterior to the ramus, various mandibular attachments blood vessels, nerves and periodontal structures. The firm attachment of the mandibular periosteum at the inferior border serves to prevent the extension of infection inferiorly into the neck.

Origin

- **Fracture or direct extension**—infection may arise from fracture or by direct extension from the floor of mouth, lateral pharyngeal spaces and masticator space.
- **Dental, periodontal or blood born**—infection may be dental, periodontal or vascular in origin.

Clinical Features

- **Location of swelling due to infection from incisor, canine and cuspid teeth**—swelling can be present in different location, according to origin of infection. Infection from incisors, cuspid or bicuspid teeth also can cause infection of space of the body of mandible.
 - **Outer cortical plate involvement**—if outer cortical plate is involved then there is induration or fluctuation of the labial sulcus.
 - **Inner cortical plate involvement**—when the inner cortical plate is involved, the infection is restricted to the floor of mouth (**Fig. 19-43**).

Fig. 19-43: Swelling seen floor of mouth due to space for body of mandible infection

- **Location of swelling due to infection from molar teeth:**
 - **Perforation of infection above the external oblique ridge**—if the infection perforates the bone above the external oblique, swelling in the oral vestibules occurs.
 - **Perforation below the mylohyoid line**—if the perforation is below the mylohyoid line the infection may point in the skin.

Submental Space

Anatomy

- *Location*—this space lies in the midline between *symphysis menti* and the hyoid bone.
- *Content of space*—it contains submental lymph nodes, which drain the median part of lower lip, tip of tongue and floor of mouth.
- *Boundaries*—it is bounded by:
 - *Floor*—its floor is formed by the mylohyoid muscle.
 - *Roof*—its roof is formed by suprahyoid portion of investing layer of deep cervical fascia.
 - *Lateral*—laterally by anterior belly of digastric muscle.

Clinical Features

- *Location of swelling*—chin becomes grossly swollen, quiet firm and erythematous.
- *Symptoms*—in some cases it may cause dyspnea and dysphagia.
- *Signs*—slight extraoral swelling just below the chin is evident (Fig. 19-44).

Fig. 19-44: Submental space infection showing swelling below the chin

Submandibular Space

Anatomy

- *Location*—it lies lateral to submental space.
- *Contents of this space*—it contains superficial part of submandibular salivary gland and its lymph nodes, the facial artery deep to the gland, proximal portion of the Wharton's duct, the lingual and hypoglossal nerve as they course deep to the gland and facial vein superficial to the gland.
- *Boundaries*—it is bounded by:

- *Laterally* by submandibular skin, superficial fascia, platysma muscle, superficial layer of deep cervical fascia and lower border of mandible.
- *Medially*—by mylohyoid, hyoglossus and styloglossus muscle.
- *Inferiorly*—by anterior and posterior bellies of digastric muscle.
- *Posteriorly*—the space extends to the hyoid bone.

Origin

Odontogenic infection of this space is caused by 2nd and 3rd mandibular molars.

Clinical Features

- *Location of swelling*—it produces a swelling near the angle of the jaw (Fig. 19-45).
- *Signs*—swelling is brawny edematous in appearance. After some days, swelling becomes soft and fluctuant.
- *Gland and lymph node involvement*—as this space lies in close proximity with submandibular gland and lymph node there is always chance of involvement of gland and lymph nodes. This will result in sialadenitis and lymphadenitis.

Fig. 19-45: Submandibular space infection showing swelling at angle of mandible

Sublingual Space

Anatomy

- *Location*—it lies above the mylohyoid muscle.
- *Contents of space*—it contains sublingual gland, submandibular duct, deep portion of the submandibular gland, lingual and hypoglossal nerves and terminal branches of lingual artery.
- *Boundaries*—it is bounded by:
 - *Superiorly*—its roof is formed by mucous membrane of the floor of mouth.
 - *Anteriorly and laterally* by inner surface of the body of mandible above the mylohyoid line.

- *Medially*—by geniohyoid, genioglossus muscle and median raphe of tongue.
- *Posteriorly*—by hyoid bone.
- *Inferiorly*—the floor is formed by mylohyoid muscle.

Origin

The infection may arise directly from perforation of the lingual cortical plate, above the mylohyoid attachment or by extension from other spaces, primarily submandibular space.

Clinical Features

- *Location of swelling*—brawny erythematous tender swelling of the floor of mouth is present. Swelling is close to mandible and spreads towards midline or beyond (Fig. 19-46).
- *Symptoms*—elevation of the tongue may be noted in late cases. Dysphasia and dyspnea may be the related complains.

Fig. 19-46: Sublingual space infection showing swelling in floor of mouth

Submasseteric Space

Anatomy

- *Location*—it includes sub-periosteal region of mandible and facial sling, containing ramus of mandible and muscles of mastication. This space is formed by splitting of the investing layer of deep cervical fascia. The splitting occurs as the fascia is attached to the lower border of the mandible.
- *Content of space*—it contains muscles of mastication, internal maxillary artery and mandibular nerve.
- *Boundaries*—it is bounded by:
 - *Anteriorly* by body of mandible.
 - *Posteriorly* by parotid space.
 - *Medially*—lateral pharyngeal space.

- *Superiorly*—it is continuous with superficial and deep temporal pouches.

Clinical Features

- *Location of swelling*—the swelling may be either external or internal, or both.
- *External swelling*—the external swelling consists of brawny induration over the ramus and angle of mandible (Fig. 19-47).
- *Internal swelling*—internal swelling may predominate in some cases. Such swelling involves the sublingual region and the pharyngeal wall. The pharyngeal swelling pushes palatine tonsils towards midline.
- *Symptoms*—pain is excruciating and often radiates to the ear. Dysphagia may be present, especially when the swelling is internal.
- *Trismus*—clinically masticatory space infection is likely to be marked by severe trismus because of irritation of masseter and medial pterygoid. It can be so severe that the mouth opening is restricted only to half a centimeter.
- Lateral pharyngeal wall, behind the palatine tonsil, is not swollen, which will help to differentiate between it and lateral pharyngeal space infection.

Fig. 19-47: Submasseteric infection showing swelling over the ramus of mandible.

Temporal Space

Anatomy

- *Location*—these are the facial spaces in relation to temporalis muscle. They are two in number, i.e. superficial and deep.

- *Superficial temporal space* lies between the temporal fascia and temporalis muscle.
- *The deep temporal pouch* lies deep to the temporalis muscle, between the latter and the skull.
- *Content*—it contains pterygoid plexus, internal maxillary artery, mandibular nerve and external pterygoid muscle.
- *Boundaries*—it is bounded by:
 - *Anteriorly*—it is bounded by maxillary tuberosity.
 - *Posteriorly*—it is bounded by lateral pterygoid muscle, condyle, and temporal muscle.
 - *Laterally*—lateral pterygoid plate, and inferior belly of lateral pterygoid muscle.

Clinical Features

- *Location of swelling*—in case of infection with superficial temporal space, swelling is limited below by the zygomatic arch and laterally, it is limited by the outline of superficial and temporal line (**Fig. 19-48**). A deep temporal abscess produces less swelling than one involving the superficial temporal space. Since it lies deep to temporalis muscle, fluctuance is difficult to elicit.
- *Dumble shaped appearance*—when it is associated with buccal space infection, the swelling has a characteristic *dumble shaped appearance* caused by the lack of swelling over the zygomatic arch.
- *Symptoms*—due to limited distensibility of temporal fascia, the pain is severe.
- *Trismus*—it is a common finding.

Fig. 19-48: Infratemporal space infection showing swelling zygomatic arch area.

Pterygomandibular Space

Anatomy

- *Location*—it is a well defined space between the mandibular ramus and pterygoid muscle.
- *Contents of space*—it contains variable amount of fat, inferior alveolar nerve and maxillary artery.
- *Boundaries*—it is bounded by:
 - *Lateral wall*—its lateral wall is formed by inner surface of ramus of mandible.
 - *Medial wall*—its medial wall is formed by medial pterygoid muscle.
 - *Roof*—its roof is formed by inferior head of lateral pterygoid muscle.
 - *Frontal section*—in frontal section the pterygomandibular space is a triangular space narrowing downward, where medial pterygoid converges with the mandible.
 - *Posterior*—posteriorly, with retromandibular space containing parotid gland.
 - *Anterior*—anteriorly, the pterygomandibular space is accessible between the deep tendon of temporal muscle, which is attached to the temporal crest of the mandibular ramus and anterior border of pterygoid muscle.

Clinical Features

- *Location of swelling*—there is no external evidence of swelling. Intraoral examination reveals an anterior bulging of half of the soft palate.
- *Signs*—deviation of tongue to the affected side.
- *Symptoms*—severe trismus and difficulty in swallowing.

Lateral Pharyngeal Space

It is also called as '*parapharyngeal space*', '*pharyngomaxillary*' or '*pterygopharyngeal space*'.

Anatomy

- *Location*—it is a lateral neck space whose shape is that of an inverted cone, with the base at the skull and its apex at the hyoid bone. Its medial wall is continuous with the carotid sheath and lies deep to the pharyngeal muscle. It is situated between the lateral wall of pharynx and fascia covering the pterygoid muscle.
- *Contents of space*—it contains fat, muscles and lymph nodes, connective tissue, cranial nerve IX and XII, carotid artery, internal jugular vein and vagus nerve.
- *Boundaries*—it is bounded by:
 - *Laterally*—by carotid sheath, internal pterygoid muscle and mandibular ramus.

- *Medially*—by lateral wall of pharynx and stylohyoid muscle.
- *Anteriorly*—by buccopharyngeal aponeuroses, parotid gland and external pterygoid muscles. It is limited by pterygomandibular space.
- *Posteriorly*—by prevertebral fascia. It communicates with retropharyngeal raphe.

Origin

The source of infection is 3rd molars and sometimes, 2nd molars, particularly by way of infection in the submandibular space or by direct extension the tooth.

Clinical Features

- *Location of swelling*—if the infection is confined to the anterior compartment, external swelling occurs anterior to the sternocleidomastoid muscle. The swelling is first seen at the angle of mandible and in the submandibular region.
- *Symptoms*—there is severe pain on the affected side of throat. Pain is sometimes referred to the ears. Infection of space occurs with abscess formation, which may impinge on pharynx and result in pain while swallowing and making it impossible. Patient also complaint of trismus irritation of medial pterygoid muscle.
- *Signs*—internally, the anterior part of lateral pharyngeal wall is swollen and it pushes the palatine tonsils together, with the soft palate towards the mid line.
- *Posterior compartment involvement*—with infection of posterior compartment, the clinical picture is marked by septicemia.
- *Complication*—respiratory paralysis resulting from acute edema of larynx. There is also thrombosis of internal jugular vein and erosion of internal carotid artery. The lateral pharyngeal space communicates with the mediastinum by prevertebral fascia, so the infection may reach to this area as direct extension.

Retropharyngeal Space

Anatomy

- *Location*—it is situated between the posterior walls of pharynx and prevertebral fascia, extending from the base of the skull to mediastinum.
- *Boundaries*—it is bounded by
 - *Laterally*—it is bound by lateral pharyngeal space and on each side by carotid sheath.
 - *Anteriorly*—by the wall of pharynx.
 - *Posteriorly*—by prevertebral fascia.
- *Danger space*—infections in this region are dangerous because of ease of spread to mediastinum and for this reason, this space is termed as danger space.

Origin

Infection result due to medial extension of infection in the lateral pharyngeal space.

Clinical Features

- *Age*—these infections are classically seen in children less than 5 years.
- *Cause*—these are generally due to otitis media and pharyngitis.
- *Symptoms*—patient will have pain, dysphagia and nuchal rigidity.
- *Signs*—there is bulging of posterior pharyngeal wall. Prominence is noted on one side due to adherence of median raphe or prevertebral fascia.
- *Radiographic finding*—it will show widened retropharyngeal space. Computed tomography can be used to diagnose this condition (**Fig. 19-49**).
- *Complication*—infection may be spread to mediastinum, causing mediastinitis.

Fig. 19-49: Computed tomography showing air spaces seen in fascial space infection.

Management of Facial Space Infection

- *Medicinal treatment*—it consist of antibiotic and analgesic therapy. Most commonly given antibiotics are penicillins, amoxicillin and ornidazole. In severe cases cephalosporins group antibiotics should be given. Usually combination of antibiotics should be given.
- *Supportive therapy*—adequate hydration, rich nutritional supplements and treatment of pre-existing diseases.
- *Extraction*—extraction of offending tooth should be carried out.
- *Incision and drainage*—surgical evacuation of pus is necessary for two reasons, i.e. to prevent further burrowing of the purulent mass, in an attempt towards spontaneous evacuation and to avoid dreaded

complications like airway embarrassment or erosion of major vessels. Technique for incision and drainage is described below.

- *Preparation of skin*—the skin is prepared in aseptic manner and prepared area is draped with sterile towels.
- *Local anesthesia*—if local anesthetic is used, a ring block of peripheral skin wheel is made for skin anesthesia.
- *Site of incision*—it should be made in the most dependent part of the abscess than in the center where the abscess points through the skin by necrosis of overlying tissue. This provides dependent drainage, avoids puckering of skin and excessive contracture of scar. Hence, it is advised to place incision on healthy skin or mucosa so that tissue heals with flat linear scar, which is more acceptable. Secondly, the incision should be placed in cosmetically and functionally acceptable place.
- *Blunt dissection* is done after an initial sharp incision through skin or mucosa. Blunt dissection by sinus forcep is performed by gentle poking and opening beaks of the instrument, until the abscess cavity is reached. Within the tissue, the beaks of the sinus forceps should never be closed together as it may crush any vital structure. The direction in which the beaks of sinus forcep are spread apart is important. This should be done parallel to the important vital structures so that if they are encountered, they are stretched rather than torn.
- *Dissection*—dissection should be extended to the alveolar process overlying the roots of the involved teeth, i.e. the source of infection.

Fatal Complications of Oral Infection

Bacterial Meningitis

It is the most common neurologic complication resulting from oral and maxillofacial infections. In this condition, bacteria infect arachnoid pia mater and CSF. The infection quickly spreads from its point of origin, via CSF, to the entire subarachnoid space.

Clinical Features

- *Symptoms*—headache, chills, fever and nausea. Pain in back and stiffness of neck.
- *Signs*—Kernig's sign (restriction of knee movement when hips are flexed due to spasm of hamstring) and Brudzinski's sign like neck sign (on flexing neck there is flexion of the hips and knee), leg sign (on flexing one leg,

the other leg also flexes) and cheek sign (pressure against cheek below zygoma will cause reflex flexion at elbow with upward jerking of the arm) are positive.

- *Diagnosis*—diagnosis is made by lumbar puncture and CSF examination.
- *Microorganisms responsible*—*Staphylococcus*, *Streptococcus*, pneumococci, *Proteus*, *Klebsiella* and *H influenzae* are common pathogens causing meningitis secondary to head and neck infection.

Diagnosis

- *Clinical diagnosis*—positive Kernig's and Brudzinski's sign is positive.
- *Laboratory diagnosis*—diagnosis is made by lumbar puncture and CSF examination.

Management

- It is a medical emergency and prompt intravenous antibiotics should be started, after antibiotic sensitivity testing.

Brain Abscess

It can develop from bacteremia associated with odontogenic infections.

Pathogenesis

- Once the bacteria reach the brain tissues →it results in local cerebritis →inflammatory exudate collects along with degenerative leukocytes →septic thrombosis of blood vessels occurs →cerebral edema develops around the infected area →as the abscess grows, its center becomes pus filled with a capsule of granulation tissue at its periphery →as the abscess increases in size, it may rupture into the ventricular system and the result is usually fatal →if it extends to subarachnoid space, meningitis may develop.

Clinical Features

- *Symptoms*—headache is due to rise in intracranial pressure. Nausea, convulsions and vomiting may occur. Dysphagia and visual defects are seen, if it involves the temporal lobe.
- *Signs*—papilloedema and convulsions are common. Hemiparesis, if abscess is on motor cortex. Confusion and stupor, if abscess is in frontal lobe.
- *Diagnosis*—diagnosis is made by radionuclide scanning and CT scanning.

Diagnosis

- *Clinical diagnosis*—papilloedema, convulsion dysphagia can give clue to diagnosis.

- *Laboratory diagnosis*—diagnosis is made by radionuclide scanning and CT scanning.

Management

- *Drainage*—drainage of the abscess via catheter through a bur hole is the treatment of choice. Once the size of the abscess is decreased the complete capsule should be excised.
- *Craniotomy*—some surgeons prefer to do craniotomy initially and then excise the entire abscess.

Cavernous Sinus Thrombosis

It is one of the most dreaded and life threatening complication due to intracranial spread of infection from odontogenic source.

Anatomy

- *Location*—they are paired sinuses situated on either side of sella turcica on lateral slopes of sphenoid bone. Each sinus is an irregularly shaped space within the dura, between the body of the sphenoid bone and medial border of middle cranial fossa.
- *Extent*—it extends from superior orbital fissure to the apex of petrous portion of temporal bone. It has anastomosis anteriorly and inferiorly with pterygoid plexus through foramen of vasallus, foramen ovale and foramen lacerum.
- *Nerve passing through sinus*—the oculomotor and trochlear nerves, the ophthalmic and maxillary divisions of trigeminal nerve passes through the sinus on the lateral wall. The abducens nerve and internal carotid artery, with its surrounding sympathetic plexus, is suspended in the sinus between the lateral wall and sphenoid bone. The blood in the sinus flows around these structures, but are separated from each other by fibrous sheath.

Etiopathogenesis

- *Infection of maxillary premolar and molar teeth*—infection from tooth may perforate buccal cortical plate. Then infection reaches to the maxillary sinus, pterygopalatine space, reaching the orbit via inferior orbital fissure. After this, infection can spread to cavernous sinus at cranial vault and results in cavernous sinus thrombosis.
- *Infection from maxillary anterior teeth*—in this, infection spread to sinus through canine space.
- *Septic emboli*—bacteria can reach cavernous sinus in septic emboli through venous and arterial systems. Septic thrombophlebitis of emissary veins can directly lead to this phenomenon.
- *Infratemporal space infection*—it can also result from direct extension through skull, by an abscess located in deep spaces such as in infratemporal space.

- *Direct antral infection*—the direct antral infection may also give rise to this disease.

Bacteriology

Many organisms have been found in culture of CSF including pseudomonas, corynebacterium, *Staphylococcus albus*, *Streptococcus*, *Diplococcus pneumonia* and *proteus*. Most common organism is *Staphylococcus aureus*.

Clinical Features

- *Symptoms*—there is high spiking fever.
- *Signs*—signs of meningeal irritation including severe headache, stiffness of neck, ocular palsy and facial weakness.
- *Eye*—proptosis or protrusion of eye is seen as a result of decreased venous drainage, chemosis and edema of eyelid, which is secondary to venous stasis.
- *Cranial nerve involvement*—limitation of extraocular movements because of involvement of 3rd, 4th and 6th cranial nerves.
- *Cranial nerve palsy*—cranial nerve palsy of 3rd, 4th and 6th nerve is usually evident due to irritation caused by pressure of venous congestion.
- *Progress*—rapid progression of signs and symptoms from one eye to other eye, due to spread of infection through inter-cavernous sinus.

Diagnosis

- *Clinical diagnosis*—cranial nerve palsy, eye involvement, limitation of extraocular movement will give clue to the diagnosis.
- *Laboratory diagnosis*—lumbar puncture should be made. CSF shows neutrophils, decreased glucose concentration and elevated protein concentration.

Management

- *Antibiotics*—massive doses of antibiotics, with proper surgical intervention at the primary site of infection are essential. The initial drug of choice is IV chloramphenicol 1gm, after every 6 hours. An attempt should be made to identify the causative organism by culture from the source of infection or from blood culture, so that precise antibiotic sensitivity is established.
- *Anticoagulant therapy*—use of anticoagulant therapy to prevent further thrombosis and dissemination of septic emboli. But some investigator think that emboli limit the infection and use of anticoagulant may promote hemorrhagic lesion in orbit and brain.

Odontogenic Infection of Orbit

It can result in significant morbidity and mortality.

Etiology

- *Infection from premolar and molar*—odontogenic infection can spread to orbit through several routes. Infection of premolars and molars can perforate the maxillary buccal plate and can spread to pterygopalatine and infra-temporal fossa and reach the orbit, via inferior orbital fissure.
- *Maxillary anterior teeth*—the maxillary anterior teeth can produce orbital cellulitis by retrograde spread through vessels like anterior facial, angular and ophthalmic vein.

Clinical Features

- *Progress*—progress of orbital infection posteriorly may involve the superior orbital fissure and spread to cavernous sinus via superior ophthalmic vein (**Fig. 19-50**).
- *Symptoms*—it may result in temporary loss of visual acuity. Long-term ophthalmologic sequelae include permanent loss in visual acuity, residual proptosis, diplopia and blindness.
- *Signs*—swelling is seen in orbital region.
- *CNS involvement*—when later CNS is involved, hemiparesis, seizures and death have also been reported.

Fig. 19-50: Swelling seen in orbital region due to odontogenic infection of molar.

Diagnosis

- *Clinical diagnosis*—temporary loss of visual acuity with swelling in orbital region.

Management

- *Antibiotic*—when orbital infection is suspected, early aggressive antibiotic therapy and surgical intervention, following appropriate consultation, should be initiated to prevent serious ocular complications and CNS involvement.

Mediastinitis

It is usually a late complication of facial infection. Acute Mediastinitis when develops as complication of odontogenic infection, is called as *descending necrotizing mediastinitis (DNM)*. Such patient may have fulminating course and leading to death.

Pathogenesis

The process occurs because it gives a pathway for spread of pus and infection from submandibular region, floor of mouth and from all the related spaces in neck, beneath the investing layer to deep cervical fascia.

Following this pathway, infection can come into close relationship with trachea, larynx and great vessels and eventually reach the mediastinum.

The most common anatomic pathway is lateral pharyngeal space, through visceral space inferiorly, which may occur causing weakening and rupture of pleura.

Clinical Features

- *Symptoms*—patient complaint of face swelling, swallowing difficulty. Usually, there is chest pain and severe dyspnea with intermitting fever and evidence of swelling on the lateral aspect of neck of the affected side. Involvement of one or two facial spaces is usually preceded by these signs and symptoms.
- *Signs*—progressive septicemia, mediastinal abscess, pleural effusion, empyema, compression of mediastinum veins with decreased venous return to heart and pericarditis may occur, with death as the final step.
- *Hemorrhage*—hemorrhage secondary to erosion of internal carotid artery or one of its branches is the most common cause of death in deep space infection.

Radiological Features

- *CT scans*—this is more precise and accurate method than conventional radiography. On CT scan extent of necrosis can be determined.

Diagnostic Criteria for Diagnosis of DNM

- Clinical evidence of severe oropharyngeal infection.
- Characteristic radiological features of mediastinitis.
- Documentation of necrotizing mediastinitis infection at the operation or postmortem.
- Establishment of relationship between DNM and oropharyngeal process.

Management

- *Airway management*—utmost priority is to be given for airway control. In such cases, either emergency tracheostomy or cricothyroidectomy may be performed.

- **Antibiotics**—specific antibiotic therapy in high doses intensive antibiotic therapy instituted. Most commonly used antibiotics are MEPM which is carbapenem antibiotics. It should be used with cilastatin. Other antibiotics which can be used is clindamycin.
- **Surgical drainage**—the initial surgical drainage and debridement must be performed upto full extent.

Septicemia and Bacteremia

- **Bacteremia**—it refers to the circulation of bacteria in blood. Transient bacteremia is frequent even in healthy persons. In such cases, bacteria, are mopped up by circulating phagocytic cells and are unable to initiate infection.
- **Septicemia**—it implies overwhelming bacterial proliferation and release of toxins in blood. There is source of infection, hypotension and pyrexia with rigors.
- **Septic shock**—it refers to a condition of shock, secondary to sepsis. It is characterized by inadequate perfusion of tissue, which occurs due to septicemia with gram-negative infection. The inadequate perfusion of oxygen in the tissues is attributed to primary cellular defect in the utilization of oxygen, due to direct effect of sepsis. Despite the better understanding of this entity, newer treatment regimens and development of more potent antibiotics. Mortality rate remains above 50%. Majority of the septic processes that result in shock usually involve gram-negative bacteria. This shock state may also be caused by gram-positive bacteria.
- **Hyperdynamic shock**—hyperdynamic changes are altogether different from that of gram-negative sepsis and shock. Usually, there is hypotension, low peripheral resistance, peripheral vasodilation and normal cardiac output. This state of shock is characterized by dry warm skin. The so called *warm shock* is readily corrected by use of appropriate antibiotics and correction of fluid volume deficit. Patient response is favorable and survival rate is substantially high.
- **Gram-negative sepsis and shock**—this type of shock occurs when severe sepsis or endotoxemia is allowed to persist. The capillary membrane starts to leak and endotoxin is absorbed into blood, leading to generalized inflammatory state. Generalized capillary leakage and other fluid losses lead to severe hypovolemia, hypotension, reduce cardiac output, high peripheral resistance and peripheral vasoconstriction. A systemic infection results in cardiac depression, pulmonary hypertension, pulmonary edema and hypoxia, which in turn reduce the cardiac output. Progressive pulmonary insufficiency is characteristically seen. If infection is not controlled, there is rapid deterioration of pulmonary function, which leads to severe hypoxemia and death. The patient becomes cold, clammy, drowsy and tachypneic.

Necrotizing Fasciitis

This condition was first recognized in 1924 by Meleney. It is defined as rapidly progressing necrosis of subcutaneous tissue and fascia, usually sparing the muscles and accompanied by toxicity, high fever and apathy. Necrotizing Fasciitis is an inflammation of the connective tissue, which may be caused by streptococcal or other types of infection, an injury, or an autoimmune reaction.

Etiopathogenesis

- **Microorganism**—the usual cause is a mixture of aerobic and anaerobic organisms. Streptococcus A group is responsible.
- **Extension of organism to the subcutaneous tissue**—the organisms reach the subcutaneous tissue by extension from a contiguous infection or trauma to the area, including surgery.
- **Dermal gangrene**—there is widespread damage to the surrounding tissue, and occlusion of small subcutaneous vessels leads to dermal gangrene.
- **Risk factors**—the presence of diseases such as diabetes mellitus, malignancy and drug addiction, are significant risk factors.

Clinical Features

- **Symptoms**—the classic warning signals are unusually severe pain at the site of a wound or cut, or in the lymph nodes, and flu-like symptoms, surfacing a few hours after an injury or surgical operation.
- **Signs**—a tender erythematous cellulitis with ill defined margins develop. The affected area of skin becomes anesthetic, secondary to cutaneous nerve destruction, which can occur before clinical gangrene.
- **Progress**—the progression of disease can alarmingly rapid with skin color changing from red blue to grey in as early as 36 hours leading to frank cutaneous gangrene due to thrombosis of nutrient vessels, usually by 4th or 5th day.
- **Skin**—skin bullae may develop, but lymph adenitis is usually not seen. Skin death subsequent to subcutaneous necrosis is common (**Fig. 19-51**).

Diagnosis

This problem is diagnosed both clinically by an experienced clinician, based upon the rapid and severe progression of an infection, and by culturing the offending bacteria.

Management

- **Antibiotics**—spectrum of antibiotics should include drugs active against anaerobic organisms such as metronidazole.

Fig. 19-51: Necrotizing fasciitis showing destruction of subcutaneous tissue and exposing the bone.

- *Surgical debridement*—extensive surgical incision and debridement is the mainstay of treatment.
- *Hyperbaric oxygen therapy*—hyperbaric oxygen therapy has been used, but its value is not proven.
- *Supportive method*—blood transfusion and general supportive measures must be given.
- *Split skin graft*—as soon as disease is controlled split skin graft should be applied, if necessary for reconstruction.
- *Wound care*—continuous wound care is of utmost important. Wounds and cuts be well cleansed, kept scrupulously clean, disinfected. Minor wounds are best cleaned with soap and water, avoiding creams and ointments. Dressings put on wounds should be sterile and act as a filter—keeping out bacteria but allowing air to reach the wound. If sweat cannot evaporate and the cut stays moist, infection easily sets in, and bandaged. Irrigation with hydrogen peroxide, followed by dressing of charcoal lime and boric acid solution soaked gauze should be applied.

Pulpal Infection

Necrosis of Pulp

It is the death of pulp. It may be partial or total depending on whether a part or the entire pulp is involved.

Etiology

- *Trauma*—it is sequelae of inflammation and can also occur following trauma, in which the pulp is destroyed before an inflammatory reaction.

Types

- *Coagulation necrosis*—the soluble portion of tissue is precipitated or is converted into a solid material.

Caseation is a form of coagulation necrosis in which the tissue is converted into a cheesy mass consisting chiefly of coagulated proteins, fats, and water.

- *Liquefaction necrosis*—it results when proteolytic enzymes convert the tissue into softened mass, liquid or amorphous debris.

Clinical Features

- *Symptoms*—it does not cause painful symptoms.
- *Sign*—discoloration of the tooth is the first indication that the pulp is dead.
- *Thermal testing*—the tooth with partial necrosis can respond to thermal changes owing to presence of vital nerve fibers passing through the adjacent inflamed tissue.

Diagnosis

- *Clinical diagnosis*—history of severe pain lasting from a few minutes to a few hours, followed by complete and sudden cessation of pain.
- *Laboratory diagnosis*—there is necrotic pulp tissue, cellular debris and microorganisms may be seen in the pulp cavity. The periapical tissue may be normal or slight evidence of inflammation of the apical periodontal ligament may be seen.

Management

- *Root canal treatment*—preparation and obturation of root canals.

Pulp Calcifications

Various forms of pulp calcifications are found within the pulp which may be located in the pulp chamber or in the root canals. It can occur in any sex and in any teeth in the dental arch.

Etiology

- *Infection*—there is no clear-cut etiology. There is no relation between pulpal inflammation and irritation, as that arising from caries or trauma, since pulp calcification can be found in unerupted teeth. Extremely high percentage of pulp stones yield pure growth of streptococci on culture but often the affected teeth are normal.
- *Sundell schematic presentation*—local metabolic dysfunction → trauma → Hyalinization of injured cell → vascular damage → thrombosis vessel wall damage → fibrosis → mineralization (nidus formation) → growth → pulp stones.

Classification

- *Discrete pulp stones (denticles, pulp nodules)*—it is of following types:

- **True denticles**—they are made up of localized masses of calcified tissue that resembles dentin due to their tubular structure. Tubules are irregular and few in number. More common in pulp chamber than root canals. They are subdivided into:
 - *Free denticle*—denticle lying entirely within pulp tissue and is not attached to the dentinal wall.
 - *Attached denticle*—these are continuous with the dentinal wall.
- **False denticle**—it is composed of localized mass of calcified material and they do not exhibit dentinal tubules. Nodule appears to be made up of concentric layers or lamellae deposited around a central nidus. It is composed of cells around which laid down is a layer of reticular fibers that subsequently calcifies. They are again classified as free or attached. They are larger than true denticles and they may fill nearly the entire pulp chamber.
- **Interstitial denticle**—as the concentric deposition of calcified material continues, it approximates and finally is in apposition with the dentinal wall where it may be surrounded by secondary dentin, then is called as an interstitial denticle.
- **Diffuse calcification**—it is also called as 'calcific degeneration'. It is amorphous unorganized linear strands or columns parallel with blood vessels and nerves of pulp.

Clinical Significance

- **Symptoms**—sometimes, it may cause pain from mild pulpal neuralgia to severe excruciating pain resembling that of *tic douloureux* as the denticle can impinge on the nerve of the pulp.
- **Difficulty in root canal treatment**—difficulty may be encountered in extirpating the pulp during root canal therapy.

Radiographic Features

- **Appearance**—they are seen as radiopaque structures within the pulp chamber (**Fig. 19-52**), in the root canals or extending from pulp chamber into root canals.
- **Shape**—they may be round or oval. Their outline varies from sharply defined to more diffuse margins.
- **Location**—they may occur as single dense mass or several opacities.

Diagnosis

- **Clinical diagnosis**—it is not possible to make clinical diagnosis
- **Radiological diagnosis**—round or oval shaped radiopacity in the pulp chamber will diagnose this condition.

Fig. 19-52: Pulp stone seen as radiopacity in the pulp chamber.

Management

It is not required.

Focal Infection

Focus of infection refers to circumscribed area of tissue, which is infected with exogenous pathogenic microorganisms and which is usually located near a mucous or cutaneous surface. *Focal infection* refers to metastasis from the focus of infection, of organisms or their products that are capable of injuring tissue.

Mechanism of Focal Infection

- **Metastasis of microorganism**—it may be spread by hematogenous or lymphogenous route. They get localized in tissues. Certain organisms have a predilection for isolating themselves in specific sites of the body.
- **Toxin and toxin products**—it is spread by bloodstream or lymphatic channels, from focus to a distant site, where they may initiate hypersensitive reaction in the tissues. One example is scarlet fever, which is due to erythrocyte toxin liberated by the infective streptococci.

Oral Foci of Infections

- **Infected periapical lesion**—particularly, those of chronic nature an area usually surrounded by the fibrous capsule, which effectively walls off or separates the area of infection from the adjacent tissues but do not prevent the absorption of bacteria or toxins. Periapical granuloma has been described as a manifestation of vigorous body defense and repair reaction, while cysts merely a progressive form of granuloma. Abscess occurs when the reparative and defensive phase is minimum.

Majority of investigators indicate that an unusually high percentage of periapical granuloma are the biologically sterile and for this reason the possibility such lesions giving rise to focal infection is minimum.

- *Teeth with infected root canals*—these are potential sources of dissemination of microorganisms and toxins. Most commonly it shows occurrence of a hemolytic streptococcus; which is the most important in etiology of rheumatoid arthritis and rheumatic fever.
- *Periodontal disease*—it is equally significant as potential source of infection. The usual organism recovered is *Streptococcus viridans*. Simple massage of gingiva may result in transitory bacteremia. The rocking of teeth in their socket by forceps, before extraction, has been shown to favor bacteremia in patients who have periodontal disease. Due to pumping action during extraction microorganism may be forced from the gingival cervix into the capillary of gingiva as well as into the pulp of tooth and thus, will result in bacteremia. Oral prophylaxis may be followed by bacteremia. So it is mandatory to administer the antibiotics to the children who are diagnosed rheumatic or congenital heart disease; to prevent the positive consequences of bacterial endocarditis.

Significance of Oral Foci of Infection

There are reports that the oral foci of infection either cause, or aggravate many systemic disorders. Most common are as follows:

- *Arthritis*—it includes rheumatoid and rheumatic fever type. Arthritis of rheumatoid type is of unknown etiology. These patients have high antibody titer to group of hemolytic streptococci. It is tissue hypersensitive reaction.
- *Points in favor of septic foci theory*—certain point like streptococcal infection of throat, tonsils or nasal sinus may precede the initial or recurrent attack. Dramatic improvement occurs sometimes after the removal of septic foci. Temporary bacteremia may occur immediately after tonsillectomy, tooth extraction or after vigorous massage of gums.
- *Points against septic foci theory*—there is no infective focus can be found. Usually when focus is extirpated, no dramatic result is found. Sulfonamide, antibiotics and vaccine have failed to produce desirable results.
- *Valvular heart diseases*—subacute bacterial endocarditis is without doubt related to oral infections. There is close similarity, in most instances, between the etiologic agent of the disease and microorganisms in the oral cavity, dental pulp and in periapical lesions. Symptoms of subacute bacterial endocarditis have been observed in some instances shortly after extraction of teeth. Transient

bacteremia frequently follows tooth extraction. Streptococci of viridan type cause majority of subacute bacterial endocarditis. After tooth extraction, there is streptococcal bacteremia, so there is occurrence of subacute bacterial endocarditis after dental operations, dental extractions. Premedication of the patient should be done before extraction.

- *Gastrointestinal disease*—some workers state that constant swallowing of microorganisms might lead to variety of gastrointestinal diseases. Gastric and duodenal ulcers are produced by injection of streptococci.
- *Ocular disease*—factor supporting the hypothesis of Woods the role of foci of infection in ocular diseases.
 - *Ocular disease without systemic cause*—many ocular diseases occur in which no systemic cause, other than presence of remote foci of infection can be demonstrated.
 - *Healing of ocular disease after removal of oral foci*—numerous instances of prompt and dramatic healing of ocular diseases are reported following the removal of these foci.
 - *Exacerbation after removal of teeth*—occasionally, sudden transient exacerbation is observed, after the removal of teeth and tonsils.
 - *Blood stream infection*—presence of blood stream infection in early stages of ocular disease, are evident.
 - *Intravenous injection of microorganism*—iritis may be produced by intravenous injection of microorganisms, e.g. streptococci.
 - *Point against this theory*—many healthy people have focal infections, but do not have ocular diseases. Spontaneous cure may occur if nothing is done. Positive blood cultures are rare in acute iritis.
- *Skin diseases*—some forms of eczema and possibly urticaria, can be related to oral foci of infection. If the relationship does not exist, the mechanism is probably sensitization, rather than metastatic spread of the microorganisms.
- *Renal disease*—microorganism most commonly involved in urinary infection are *E.coli*, staphylococci and streptococci. Streptococci hemolyticus seems to be the most common. Streptococci are uncommon inhabitants of dental root canals or periapical and gingival areas. Since the microorganisms are commonly involved in renal infection, it appears that there is little relationship between oral foci of infection and renal disease.

Pits, Fistulae and Draining Sinus of Oral Cavity

- *Fovea palatini*—they are two indentations formed by coalescence of several mucus gland ducts near midline

of the palate. There is round to oval depressions always located in soft tissue on anterior part of soft palate. Depth of fovea is about 0.5 to 2 centimeters. It is accentuated when patient holds his nose and attempts to blow it. When manipulated they secrete 'clear mucinous fluid'.

- *Post-surgical pit*—it is a result of breakdown of the wound secondary to infection or failure to obliterate the dead space during wound closure. Dimple or puckering of either portion or entire surface of the wound with comparatively shallow depression is present. This can be probed easily.
- *Post-infection pit*—it results from loss of tissue often due to necrosis. After infection has been resolved, subsequent invasion of surface tissue into resultant defect forms post-infection pit. Surgical elimination.
- *Oronasal fistula*—it is a pathological defect lined by epithelium connecting the oral and nasal cavity. It may be congenital, palatal trauma, infection, neoplasm and surgical procedures. Sometimes acute dentoalveolar abscess burrow through maxilla in floor of nasal cavity and it may also be produced during surgical removal of teeth, buried roots, odontomas, tori, cysts and neoplasms. Patients complain of food passing into nose and often demonstrate nasal speech. Surgical removal of fistula and subsequent flap advancement.
- *Draining cyst*—odontogenic and non-odontogenic cysts may penetrate and produce a sinus that drains into the oral mucosa. Before sinus formation there is pain and swelling of the involved area. When periosteum and mucosa perforate, the pain ceases and purulent discharge is seen. If sinus is small, drainage may continue in chronic cases, but if it is large, cyst may disappear completely due to decompression. There is expansion of cortical plates.
- *Patent nasopalatine duct*—it is a rare condition; it arises when embryonic nasopalatine duct fails to obliterate. It is tunnel shaped and is continuous with the nasal epithelium. It extends downwards in an anterior direction more or less parallel with the facial contour or pre-maxilla to exist or seen on each side of palatine papilla. It is asymptomatic.
- *Pustule*—it is a small superficial elevation of skin and mucous membrane filled with pus and becomes a draining lesion for a short time after they rupture. They result from psoriasis, impetigo, acrodermatitis enteropathica containing superficial bacterial disease. It is surrounded by erythema. It is asymptomatic, but may be tender and painful.
- *Second branchial arch sinus*—it is fairly common and it occurs when the second branchial cleft or second pharyngeal pouch or both fail to obliterate during the embryological development of the fetus. It is having familial tendency. It can be unilateral or bilateral found

at birth or within the first year of life. It opens close to anterior border of sternocleidomastoid muscle with majority being in the lower neck above the sternoclavicular joint. There is history of intermittent drainage since childhood or spontaneous discharge by infection and cervical cyst. It appears as a small dimple or small opening in lateral region of neck.

- *Salivary gland fistula and sinus*—it is rare and is caused by accidental trauma, surgery and infection. It may occur as result of actinomycosis, syphilis and *carunculus oris*. The saliva escapes from damaged ducts either from pools within soft tissue or drains through fistula in skin.

Introduction

Pigments are the colored substances, some of which are normal constituents of cells (e.g. melanin), whereas others are abnormal and collect in cells only after under special circumstances. Pigments can be *exogenous*, coming from outside in the body, or *endogenous*, synthesized within the body itself. Exogenous pigmentation is commonly due to foreign-body implantation in the oral mucosa.

Endogenous pigments include *melanin*, *hemoglobin*, *hemosiderin* and *carotene*.

In the course of disease, the oral mucosal tissues can assume a variety of discolorations blue, brown, and black discolorations constitute the pigmented lesions of the oral mucosa, and such color changes can be attributed to the deposition of either endogenous or exogenous pigments.

The most important endogenous factor causing pigmentation in the oral cavity is *melanin*. It is derived from the Greek (Melas-black), is an endogenous, non-hemoglobin derived, brown-black pigment formed when the enzyme tyrosinase catalyzes the oxidation of tyrosine to dihydroxy-phenylalanine in melanocytes. Melanin in the melanosome, the specialized epidermal melanin-bearing organelle, is responsible for the color variation of human skin.

There are generally considered to be two types of melanin pigmentation which form normal skin color. *Constitutive skin color* implies the genetically determined color of healthy unexposed skin such as observed on habitually sun-shielded areas like the buttock and inner upper arm; *facultative skin color* applies, for example, to “tanned” skin and reflects the genetic capacity of the skin to darken in response to ultraviolet radiation exposure.

Three types of melanin have been demonstrated.

- *Eumelanin*—it is brown-black melanin which is found in ellipsoid melanosomes which impart brown-black color to skin and hair.
- *Pheomelanin*—it is yellow-red melanin in spherical melanosomes which are the basis of yellow-red hair.

- *Neuromelanin*—it is black pigment formed within nerve cell by an enzymic pathway different from that responsible for eumelanin or pheomelanin formation.

The melanin producing cells, melanocytes, are highly specialized dendritic cells of neural crest origin. Melanocytes are found in humans in skin, mucous membrane, uveal tract. Melanin pigment synthesized in specialized cytoplasmic organelles called *melanosomes*, which contain the aerobic oxidase, tyrosinase, which initiates the conversion of tyrosine to melanin.

The endogenous pigmentation of the oral mucous membrane is most frequently explained by the presence of hemoglobin, hemosiderin, and melanin. Hemoglobin imparts a red or blue appearance to the mucosa and represents pigmentation associated with vascular lesions; the coloration is rendered by circulating erythrocytes coursing through patent vessels. In contrast, hemosiderin appears brown and is deposited as a consequence of blood extravasation, which may occur as a consequence of trauma or a defect in hemostatic mechanisms. Hemochromatosis (generalized hemosiderin tissue deposition) may occur as a result of a variety of pathologic states.

Essence of Oral Pigmentation

Pigmentation of the perioral and intraoral tissues is a frequent finding. Oral pigmentation may be physiologic or pathologic and the finding of oral pigmentation may represent a systemic disease of the patient. Such lesions represent a variety of clinical entities, ranging from physiologic changes (e.g. racial pigmentation) to manifestations of systemic illnesses (e.g. Addison’s disease) and malignant neoplasms (e.g. melanoma and Kaposi’s sarcoma). Finding of oral pigmentation may represent a systemic disease of the patient. Therefore, an understanding of the causes of mucosal pigmentation and appropriate evaluation of the patient are essential.

Gingival physiologic pigmentation may cause problems for some patients especially female as far as esthetics is concerned. Social behavior can be devastatingly affected by pigmentation disorder. The psychological problems arising from the pronounced cosmetic disfigurement of vitiligo patient in pigmented races are easily understood.

Definition and Terminologies Used in Pigmentation

- *Hypomelanosis*—it refers to decrease in normal melanin pigmentation.
- *Amelanosis*—It refers to total lack of melanin.
- *Depigmentation*—It refers to loss of previously existing melanin.
- *Leukoderma*—it is a generic term for skin relatively or absolutely lightened in color.
- *Poliosis*—it refers to localized whitening of hair.
- *Canities*—it refers to more generalized defect in whitening of hair.
- *Macule*—well-circumscribed, flat lesions that are noticeable because of their change from normal skin color. They may be red due to the presence of vascular lesions or inflammation, or pigmented due to presence of melanin, hemosiderin, and drugs.
- *Papules*—solid lesions raised above the skin surface that are smaller than 1 cm in diameter. Papules may be seen in a wide variety of diseases including erythema multiforme simplex, rubella, lupus erythematosus, and sarcoidosis.
- *Plaques*—solid raised lesions that are over 1 cm in diameter; they are large papules.
- *Wheal*—itchy, transient, elevated lesion with variable blanching and erythema formed as the result of dermal edema.
- *Hematoma*—it is localized collection of blood, usually clotted, in a tissue or organ.
- *Purpura*—reddish to purple flat lesions caused by blood from vessels leaking into the subcutaneous tissue. It is classified by size as petechiae or ecchymoses, these lesions do not blanch when pressed.
- *Petechiae*—purpuric lesions 1 to 2 mm in diameter.
- *Ecchymoses*—it is greater than 3 mm.

- *Burrow*—a linear or curvilinear papule, caused by a burrowing scabies mite.
- *Comedo*—a plug of keratin and sebum wedged in a dilated pilosebaceous orifice.
- *Telangiectasia*—the visible dilatation of small cutaneous blood vessels.
- *Scale*—a flake arising from the horny layer.
- *Crust*—looks like scale, but is composed of dried blood or tissue fluid.
- *Atrophy*—thinning of skin due to diminution of the epidermis, dermis, subcutaneous fat.
- *Stria*—a streak-like, linear, atrophic, pink, purple or white lesion of the skin due to changes in the connective tissue.

Classification

It is discussed in **Tables 20-1 to 20-3**.

Blue/Purple Vascular Lesions

Hemangioma

Hemangioma is a benign proliferation of the endothelial cells that line vascular channels. Vascular malformation is a structural anomaly of blood vessels without endothelial proliferation. Both lesions are developmental abnormalities, characterized by onset during infancy. Hemangioma regresses as the patient ages, but vascular malformation persists throughout life. Hemangioma of the head and neck region is relatively common, representing at least a third of all hemangiomas in humans. Oral hemangioma represents 14% of all human hemangiomas.

A simple classification is that proposed by Watson and McCarthy is as follow capillary hemangioma, cavernous hemangioma, angioblastic or hypertrophic hemangioma, racemose hemangioma, diffuse systemic hemangioma, metastasizing hemangioma, nevus vinosus or port-wine stain and hereditary hemorrhagic telangiectases.

Etiology

It is often congenital in nature and usually but not invariably follows a benign course. Some authorities believe

Table 20-1: First classification according to color

Color	Focal	Diffuse	Multifocal
Blue/purple	Varix, Hemangioma	Hemangioma	Kaposi's sarcoma, Hereditary hemorrhagic telangiectasia
Brown	Melanotic macules, nevus, melanoma	Ecchymosis, melanoma, drug induced, hairy tongue, petechiae	Physiologic pigmentation, neurofibromatosis, lichen planus, Addison's disease, drug induced, Peutz-Jegher's syndrome
Gray black	Amalgam tattoo, graphite tattoo, nevus, melanoma	Amalgam tattoo, hairy tongue	Metal ingestion

Table 20-2: Second classification

Diffuse and bilateral	Focal
• Early onset • Physiologic pigmentation • Peutz-Jegher's syndrome • Predominantly adults onset <i>With systemic signs and symptoms</i> • Addison's disease • Kaposi's sarcoma • Heavy metal pigmentation <i>No systemic signs and symptoms</i> • Smoker's melanosis • Drug-induced pigmentation • Post inflammatory pigmentation	• Red blue purple <i>Blanching</i> • Hemangioma • Varix <i>Non-Blanching</i> • Thrombus • Hematoma • Blue gray • Amalgam tattoo • Other foreign body tattoos • Blue nevus • Brown • Oral melanotic macule • Pigmented nevus • Melanoacanthoma • Melanoma

Table 20-3: Endogenous pigmentation

It is most often explained by pigments like hemoglobin, hemosiderin and melanin.		
Pigment	Color	Disease process
Hemoglobin	Blue, red, purple	Varix, hemangioma, Kaposi's sarcoma, angiosarcoma, hereditary hemorrhage telangiectasia
Hemosiderin	Brown	Ecchymosis, petechiae, varix, hemorrhage mucocele, hemochromatosis
Melanin	Brown, black, gray	Melanotic macule, nevus melanoma, basilar melanoma

the lesion, particularly the congenital form, is not the true neoplasm, but rather a developmental anomaly or hamartoma.

Clinical Features

- **Signs**—the earliest sign of a hemangioma is blanching of the involved skin, often followed by fine telangiectases and then a red macule.
- **Hemangioma in children**—rapid growth during the neonatal period is the hallmark of hemangiomas, occurring characteristically beyond the growth rate of the infant. The hemangiomas of childhood are found on the skin, in the scalp, and within the connective tissue of mucous membranes. Approximately 85% of childhood-onset hemangiomas spontaneously regress after puberty.
- **Diascopy**—diascopy usually shows blanching on pressure. This procedure is performed by pressing gently on the lesion with a glass slide or a glass test tube. A positive diascopy result (blanching) generally indicates that the blood is within vascular spaces and is displaced out of the lesion by pressure. However, lack of blanching does not exclude the possibility of a vascular lesion.

- **Color of oral hemangioma**—hemangioma of the oral soft tissue is similar to the hemangioma of the skin and appears as a flat or raised lesion of the mucosa. It is usually deep red or bluish red and seldom well circumscribed (**Fig. 20-1**).
- **Site**—the most common site of occurrence is the lips, tongue, buccal mucosa and palate. The tumor often is traumatized and undergoes ulceration and secondary infection.

Fig. 20-1: Bluish color pigmentation seen in case of hemangioma of tongue (Courtesy Dr Tapasya Karamore).

Differential Diagnosis

- **Mucocele, ranula and superficial cyst**—the hemangioma blanches and may be emptied by the application of digital pressure, which forces the blood from the vascular spaces. This feature accounts for the finding that the lesion is not fluctuant and, in turn, helps to differentiate the cavernous hemangioma from the mucocele, ranula and superficial cyst, which though soft are, in contrast, fluctuant and nonemptiable.
- **Varicosity**—a varicosity is usually seen as an elongated enlargement of superficial vein rather than as a nodule or dome shaped mass. Furthermore, a pulse is not detectable within the cavernous hemangioma.
- **Arteriovenous shunt or aneurysm**—no pulse detected in hemangioma as in case of arteriovenous shunt or an aneurysm, both of which may occur as rubbery, nonfluctuant, domelike, bluish nodules with a usually discernible throbbing.

Management

- **Sclerosing technique**—sclerosing agents such as sodium tetradecyl sulfate can be used intralesionally.
- **Cryosurgery**—it can be useful in treating hemangioma.

Varix and Varices

Varix is an enlarged and convoluted vein, artery or lymphatic vessel. It is an acquired benign vascular lesion, generally asymptomatic, and does not require treatment. Oral varix is morphologically composed by one to three extensive and tortuous blood vessels lined by flat mature endothelium.

Definition

- *Varices*—pathological dilatation of vein or venules are varices or varicosity.
- *Varix*—focal dilatation of group of venules or vein is known as varix.

Etiology

Trauma plays an important role in the development of a varix. The traumatic event probably damages and weakens the vascular wall and result in dilation.

Clinical Features

- *Location*—it is commonly found on the tongue, lip or cheek, mainly in the seventh decade of life.
- *Color*—oral varix is characterized as a red to purple papule or nodule.
- *Margins and shape*—it has sharply delineated borders and a smooth, rounded surface contour.
- *Caviar tongue*—when many of sublingual veins are involved it is called caviar tongue (**Fig. 20-2**).

Fig. 20-2: Caviar tongue appears showing many purple colored dilation of venules.

Differential Diagnosis

- *Difference between hemangioma and varix*—the varix resembles the hemangioma both clinically and histologically, yet it is distinguished by two features: the patient's age at its onset and its etiology. A hemangioma

is usually congenital and has a tendency to spontaneously regress whereas a varix arises in older individuals and, once formed, does not regress. Alternatively, a varix has a finite growth potential; once a varix has formed, further enlargement is uncommon. Whereas hemangiomas are vascular hamartomas of unknown etiology, the varix represents a venous dilatation that may evolve from trauma such as lip or cheek biting.

- *Superficial non-keratotic cyst and ranula*—it cannot be emptied by digital pressure.
- *Aneurysm*—rare and demonstrate pulse.
- *Hereditary hemorrhagic telangiectases*—it may confuse with varix but is multifocal and hemorrhagic.
- *Nevi*—nevi does not blanch on pressure and it has palpable nature.

Management

- *Surgical approach*—the lesion can be excised or removed by other surgical methods, including electrosurgery and cryosurgery.
- *Intralesional injection of sclerosing solution*—intralesional 1% sodium tetradecyl sulfate injection is effective as well, yet it is usually more painful than simple excision. This sclerosing agent should be injected directly into the lumina with a tuberculin syringe (depositing 0.05 to 0.15 mL/cm³).

Thrombus

A thrombus, or blood clot, is the final product of the blood coagulation step in hemostasis. It is achieved via the aggregation of platelets that form a platelet plug, and the activation of the humoral coagulation system (i.e. clotting factors). A thrombus is physiologic in cases of injury, but pathologic in case of thrombosis.

Specifically, a thrombus is a blood clot in an intact blood vessel. A thrombus in a large blood vessel will decrease blood flow through that vessel. In a small blood vessel, blood flow may be completely cut-off resulting in death of tissue supplied by that vessel. If a thrombus dislodges and becomes free-floating, it is an embolus.

Etiology

- *Damage to vessel*—both arterial and venous thrombosis may arise either because of damage to the vessel for instance, atheroma or varicose veins.
- *Change cellular elements*—it may result due to changes in the plasma or cellular elements.

Clinical Features

- *Color*—if the varix contain the thrombus, it presents as a firm bluish purple nodule that does not blanch under pressure.

- *Site*—thrombi are more common on the lower lip and buccal mucosa.

Management

- *Heparin and warfarin*—these are often used to inhibit the formation and growth of existing blood clots, thereby allowing the body to shrink and dissolve the blood clots through normal method.

Kaposi's Sarcoma

Synonyms: Multiple idiopathic hemorrhagic sarcoma of Kaposi's, Angioreticuloendothelioma.

Kaposi's sarcoma is an unusual and uncommon disease of blood vessels which occasionally manifests in the oral cavity: Classical (sporadic) Kaposi's sarcoma was described by Moritz Kaposi in 1872 in central Europe among elderly persons of Mediterranean or Jewish origin as a multiple pigmented sarcoma of the skin. Kaposi's is most accurately described as a multifocal angioproliferative neoplasm that primarily involves the skin in non-HIV infected person. KS is a neoplasm now most commonly a manifestation of infection with the human immunodeficiency virus (HIV), that frequently affects the oral cavity.

Although KS interaction with HIV infection remains unexplained, the epidemic occurrence of KS in patient with AIDS clearly supports a causal relationship between the immune deficiency and the appearance of this neoplasm. Pathogens or factors suspected to be associated with KS include human herpes virus type 6, cytomegalovirus, human immunodeficiency virus, mycoplasma penetons, sex hormones and nitrate inhalants. However, solid evidence of etiologic association among any of these agents with AIDS or non-AIDS KS has not been established yet.

This vascular neoplasm may present as cutaneous, oral or visceral lesion either independently or synchronously. The frequency is higher in homosexual and bisexual male than in other risk group for HIV infection: There is also an increased incidence of Kaposi's sarcoma among transplant patients, which can resolve after immunosuppression drug therapy is halted. Some investigators believe that KS is a form of vascular hyperplasia responding to endothelial growth factors rather than a malignant neoplasm.

Clinical Features

- *Age distribution and sex distribution*—KS may occur at any age, but is most common in the fifth, sixth and seventh decades. There is marked male predilection with a gender ratio of 20 to 1.
- *Appearance*—the tumor begins as a multicentric neoplastic process that manifests as multiple red/purple (vascular appearing) macules and in more advanced types, nodules, occurring on the skin or mucosal areas.
- *Progress*—the lesion tends to enlarge and become darker and may coalesce or form clusters of single nodules.
- *AIDS associated*—occurrence of KS in patient with AIDS in the head-neck area is common. The tip of the nose is a peculiar but frequent location of these. Facial, scalp, periorbital and conjunctival involvement are also typical. The neoplasm can involve lymph nodes, soft tissue of the extremities and GIT.
- *Clinical presentation*—four clinical presentation of Kaposi's sarcoma are recognized.
 - *Classic type*—classic (chronic) KS is primarily a disease of late adult life and about 90% of cases occur in man. It mostly affects individuals of Italian, Jewish or salvic ancestry. Multiple bluish purple macules and plaques are present on the skin of the lower extremities.
 - *Endemic*—endemic KS in Africa has been divided into four subtypes:
 - *A benign nodular type* similar to classic KS.
 - *An aggressive type*, is characterized by progressive development of locally invasive lesions that involve the underlying soft tissue and bone.
 - *A florid form* is characterized by rapidly progressive and widely disseminated, aggressive lesions with frequent visceral involvement.
 - *A unique lymphadenopathic type*, which occurs primarily in young black children and exhibits, generalized, rapidly growing tumors of lymph nodes, occasional visceral organ lesions and spare skin involvement.
 - *Iatrogenic type*—iatrogenic immunosuppression associated KS most often occurs in recipient's organ transplants. It affects 0.4% of renal transplant patient, usually several months to a few years after the transplant. It is probably related to the loss of cellular immunity, which occurs as a result of immunosuppressive drug.
 - *AIDS related KS*—frequently involves the head and neck.

Oral Manifestation

- *Location*—the lesions of the oral mucosa are identical in appearance with cutaneous nodules. KS can involve any oral site but most frequently involves the attached mucosa of the palate, gingiva and dorsum of tongue.
- *Appearance*—oral KS lesions occur as red to purple nodules and macule with mucosal ulceration in some of the more mature cases.
- *Symptoms*—the lesions result in pain, dysphagia, difficulty with mastication, bleeding, and may be cosmetically displeasing. This is particularly true with the progression from the flat to the nodular form, which has been associated with increasing grades of immunocompression.

- *Palpation*—the lesion does not blanch with pressure. Early lesion may appear as similar to ecchymosis or hemangioma.

Differential Diagnosis

- *Hemangioma*—it blanches on pressure.
- *Purpura*—it is presented as multiple papules on the soft palate.
- *Nevi*—it is not so aggressive lesion.
- *Melanoma*—it is not multicentric process.

Management

- *Radiation therapy*—for skin lesions in the classic form of the disease, radiation therapy often is used. Radiotherapy for oral KS is most often fractionated to result in a dose of 25 to 30 Gy over 1 week. Severe mucositis can follow radiotherapy for oral KS, although this may be less severe with fractionated treatment.
- *Surgical eradication*—surgical eradication of the disease is difficult because of the multiplicity of lesions. The carbon dioxide or argon laser can be very effective in the surgical treatment or palliation of KS involving the upper aerodigestive tract.
- *Systemic chemotherapy*—systemic chemotherapy especially vinblastine may also be helpful. If KS progresses at multiple sites, systemic chemotherapy may be needed. The most commonly used regimen is alternating weekly vinblastine and vincristine. Other effective agents include doxorubicin in low doses, bleomycin and methotrexate. Etoposide has also been used. Recombinant interferon alpha—2A and alpha—2b have been identified as efficacious agents in the treatment of KS.
- *Intralesional injection*—the intralesional use of vinblastine, in doses varying from 0.01 to 0.04mg (multiple intralesional injections), may be an effective alternative treatment for small KS lesion of the mouth. The treatment is repeated every 2-4 weeks until the remission of the tumor mass is obtained.
- *Combination therapy for AIDS related Kaposi's sarcoma*—in case of epidemic (AIDS associated) KS, a great variety of treatment regimens such as single agents, combined chemotherapy, or zidovudine with interferon—alpha and radiotherapy have been tried. Circumscribed lesions localized within the mouth and associated with a CD4 T-lymphocyte count of more than 500 cells /mL may be treated by excision, cryotherapy, or even sclerotherapy, to which they rapidly respond. At a CD4 level of fewer than 200 cells/mL, systemic chemotherapy and anti-retroviral treatment is advisable; while for intermediate CD4 counts, interferon with zidovudine may be appropriate. Prognosis is variable, depending on the form of disease and the patient's immune status.

Hereditary Hemorrhagic Telangiectasia

- *Cause*—it is a genetically transmitted disease inherited as an autosomal dominant trait.
- *Site*—there may be hundreds of such purple papules on the vermillion border and mucosal surface of lips as well as tongue and buccal mucosa.
- *Color*—papules are red or brown rather than purple.
- *Shape and size*—it is characterized by multiple, round or oval papules measuring less than 0.5 cm in diameter.
- *Management*—it can be cauterized by electrocautery.

Blue Nevus

Nevus is defined as a congenital, developmental tumor-like malformation of the skin or mucous membrane. It is a true mesodermal structure composed of dermal melanocytes which only rarely undergo malignant transformation.

The Blue nevus represents a localized proliferation of dermal melanocytes. It is an uncommon pigmented tumor of dermal melanocytes that has traditionally been classified into common and cellular variant. It is usually a skin tumor in adults but can become apparent in early childhood or even present at birth. Malignant blue nevus is a rare melanocytic tumor of the skin arising from a preexisting cellular blue nevus.

Etiology

- *Dermal arrest*—although definitive experimental evidence is lacking, blue nevi are believed to represent dermal arrest in embryonal migration of neural crest melanocytes that fail to reach the epidermis.
- *Genetic predisposition*—because of the variation of blue nevi in different populations, a genetic predisposition has been suggested. However, familial cases of blue nevi are exceedingly rare.

Clinical Features

- *Age and sex predilection*—blue nevi are twice more common in women than in men. Blue nevi may develop at any age but are usually noticed in the second decade of life or later.
- *Site*—it occurs chiefly on buttocks, on the dorsum of feet and hands, on the face and occasionally on other area.
- *Color*—the lesion is smooth, exhibits hairs growing from its surface and varies in colors from brown to blue or bluish black.
- *Appearance*—the common blue nevus is a flat to slightly elevated, smooth surfaced macule, papule, or plaque that is gray-blue to bluish black in color.
- *Tyndall effect*—the clinically noted blue color is due to the depth of melanin in the epidermis and has the Tyndall effect. The Tyndall effect is the preferential

absorption of long wavelengths of light by melanin and the scattering of shorter wavelengths, representing the blue end of the spectrum, by collagen bundles.

- *Cellular blue nevus*—the cellular blue nevus was first described as a variant of melanoma. Later, it was classified as a variant of blue nevus. Controversy still arises over the precise distinction of atypical cellular blue nevus from melanoma. The cellular blue nevus is a less common lesion but often clinically similar to the common blue nevus. These lesions tend to be large, usually measuring 1-3 cm in diameter. Lesions are elevated, smooth-surfaced papules or plaques that are gray-blue to bluish black in color. Lesions are usually solitary and found on the buttocks, the sacral region, and occasionally on the dorsal aspects of the hands and the feet.

Differential Diagnosis

- The differential diagnosis includes traumatic tattoo, pigmented basal cell carcinoma and melanoma.

Management

- *Surgical excision*—simple excision is the treatment of choice.

Brown Melanotic Lesions

Melanotic Macule

The term 'melanotic macule' has been used to describe a benign pigmented lesion of the oral cavity, characterized by an increase in melanin pigmentation along the basal cell layer of the epithelium and the lamina propria. Melanotic macules have been variously termed as *ephelis*, *melanosis*, *lentigo*, *solitary labial lentigo*, *labial melanotic macule* and *oral melanotic macules*. It represents an increase in synthesis of melanin pigments by basal cell layer melanocytes without increase in the number of melanocytes. It is the most common pigmentation to occur in oral cavity of light skinned individuals.

Etiology

- *Genetic*—controversy exists on the pathogenetic mechanism that leads to the development of melanotic macules and it is not clear if they represent a physiologic or a reactive process. Some authors reported a positive family history and a genetic predisposition has been hypothesized.
- *Racial*—if arising in children, it is most likely racial in origin, in which case it may be called racial pigmentation (Fig. 20-3) or physiologic pigmentation; no treatment is necessary.

- *Environmental factors*—when it arises in adults it may be smoke-induced, drug-induced, hormone-induced or spontaneous (without cause), and it is usually biopsied in order to be sure that it is not a malignant melanoma. Some inherited diseases show brown pigmentation of the oral membranes.

Fig. 20-3: Racial pigmentation seen on the gingiva.

Clinical Features

- *Age*—The solitary oral melanotic macule is seen in middle aged adults. Females are more affected than males.
- *Site*—it is attributed to actinic exposure and therefore occurs on vermilion border of the lower lip. Sometimes it can also occur on gingiva, palate and buccal mucosa.
- *Color and appearance*—the melanotic macule is typically a well circumscribed flat area of pigmentation that may be brown, black, blue or gray in color.
- *Size*—most of the lesions are less than 1 cm in diameter, although in occasional cases, they may be larger in size.
- *Shape*—lesions are oval or irregular in outline.

Differential Diagnosis

- *Melanoplakia*—they are larger and occur in black individuals.
- *Amalgam tattoo*—associated with juxtaposed amalgam filling.
- *Ecchymosis patch*—it has got brownish color and it usually disappears within few days.
- *Superficial spreading melanoma*—It is seen in older age group and spreads by circumferential growth. Men are more affected and palate is commonly affected site.
- *Flat nevi and lentigo*—are very rare in the oral cavity.
- *Focal melanosis*—it is not seen as pigmented lesion.

Management

- *Surgical excision*—excision with adequate borders should be carried out.

Pigmented Nevus

Nevus is the general term that may refer to any congenital lesion of various cell types or tissue types, such as epidermis, vessels, and pigment cells. It is a congenital or acquired benign tumor of melanocytes or nevus cell that occurs on skin. Oral nevi are rare. It is usually but not always pigmented, ranging from gray to light brown to blue to black. They are of four types—intramucosal, junctional, compound and blue nevus.

Etiology

- *Pigment cells*—the origin of nevus cells is not completely known. It has been postulated that they are derived from pigment cells that migrate from the neural crest to the epithelium and dermis (submucosa) or that may develop from altered resident melanocytes.

Clinical Features

- *Age*—they usually appear shortly after birth and throughout childhood.
- *Site*—it is most frequently encountered on the palate, gingiva, buccal mucosa and lip.
- *Color and appearance*—intraoral nevi are rare that may occur at any age. It is characterized by a plaque or dome-shaped sessile nodule with blue or black pigmentation (Fig. 20-4).
- *Signs*—pigmented nevi do not blanch on pressure. They generally reach a given size and then growth becomes static.

Fig. 20-4: Pigmented nevus seen on neck of patient

Differential Diagnosis

- *Vascular lesions*—these include hematoma, varix, and hemangioma. Hematoma is ruled out by history and varix and hemangioma are ruled out by diascopy (compression) method. These vascular lesions blanch on pressure.

- *Amalgam tattoo*—amalgam restoration is seen adjacent to pigmentation.
- *Melanoma*—they are rare in the oral cavity.

Management

- *Excisional biopsy*—junctional nevi in adult may evolve into malignant melanoma. For this reason, all nevi should be excised. Since their size is generally less than 1 cm, excisional biopsy would be usually indicated.

Melanoacanthoma

The term 'melanoacanthoma' was first used by Mishima and Pinkus in 1960 to describe a benign mixed skin tumor composed of basal and prickle cell keratinocytes and pigment-laden dendritic melanocytes. Oral melanoacanthoma is a rare, benign pigmented lesion, similar to cutaneous melanoacanthoma, characterized by proliferation of dendritic melanocytes scattered throughout the thickness of an acanthotic and hyperkeratotic surface epithelium.

Etiology

- The pathogenesis of oral melanoacanthoma is not clear, although its clinical behavior is suggestive of a reactive origin.

Clinical Features

- *Sex predilection*—the lesion occurs almost exclusively in blacks and has a female predilection.
- *Site*—it is seen most frequently on the buccal mucosa, which may be related to greater frequency of trauma in this area in 20-40-year-old persons. But can occur at any oral site like lip, palate and gingiva and at any age.
- *Appearance*—it is usually presenting as a single smooth, flat or slightly raised, dark brown to black macule.
- *Size*—the lesion often demonstrates an alarmingly rapid increase in size and occasionally will reach a diameter of several centimeters within a period of a few weeks.
- *Symptoms*—it is asymptomatic and not indurated.

Differential Diagnosis

- *Melanoma*—this lesion has a tendency to enlarge rapidly, which raises the possibility of a malignant process in the clinical differential diagnosis. However, its tendency to occur in young black females distinguishes it from melanoma, which is uncommon in this age and racial group.

Management

- *Incisional biopsy*—oral melanoacanthoma appears to be a reactive lesion with no malignant potential. In some cases, the lesion disappears after incisional biopsy or removal of the offending stimulus.

Melanoplakia

This term is applied to a flat, localized or widespread, black or brownish discoloration of the oral mucosa due to increased amount of melanin.

Melanin is produced by dentrite melanocytes in basal cell layer of epidermis and is formed by oxidation of tyrosine, a reaction that is catalyzed by copper containing enzyme tyrosinase and mediated by melanocytes stimulating hormone from anterior pituitary.

Etiology

- *Smoker melanosis*—it may occur due to smoker's melanosis.
- *Racial pigmentation*—it may occur due to racial pigmentation.
- *Systemic disorders*—it can also occur in diseases like Peutz-Jegher's syndrome, Addison's disease or hemochromatosis or may result from lead poisoning or cancer chemotherapy.

Clinical Features

- *Race*—dark complexioned people frequently have macular pigmentation of various sizes on their oral mucosa.
- *Color*—it varies from light brown (Fig. 20-5) to blue pigmentation depending on amount of melanin present and depth of lesion.

Fig. 20-5: Melanoplakia showing light brown type of pigmentation.

Differential Diagnosis

- *Amalgam tattoo*—tooth with amalgam filling is seen in close proximity.
- *Junctional nevus*—it is very rare in oral cavity.
- *Melanoma*—it is seen in older individuals and spread by circumferential growth.
- *Local area of hemosiderin deposit* —it is not seen as pigmented lesion.

Management

- *Biopsy*—biopsy is done if the pigmented patch appears recently rather than from birth or during childhood. It becomes elevated in part or whole lesion and increases in size and undergoes color changes and surface ulceration.

Smoker's Melanosis

Smoker's melanosis occurs in 25 to 31% of tobacco users and is characterized by discrete or coalescing multiple brown macules that usually involve the attached mandibular gingiva on the labial side, although pigmentation of the palate and buccal mucosa has also been associated with pipe smoking. Smoking-associated melanosis is due to increased melanin production by melanocytes and its deposition within the basal cell layer and lamina propria. The microscopic appearance of melanosis is essentially similar to that seen in physiologic pigmentation or a melanotic macule.

Etiology

- *Nicotine*—smoker's melanosis may be due to the effects of nicotine (a polycyclic compound) on melanocytes located along the basal cells of the lining epithelium of the oral mucosa (Fig. 20-6). Nicotine appears to directly

Fig. 20-6: Smoker's melanosis presented as black type of pigmentation.

stimulate melanocytes to produce more melanosomes, which results in increased deposition of melanin pigment as basilar melanosis with varying amounts of melanin incontinence.

- *Polycyclic amines*—Araki et al reported that polycyclic amines in tobacco, such as nicotine and benzpyrenes, stimulate melanocytes to increase their melanin production. It has been suggested that oral melanin may protect the mucosa by binding with toxic agents from tobacco smoke, which can readily penetrate into the tissue. Smoker's melanosis seems to be directly related to stimulant effect of substances in smoke on melanocytes.

Clinical Features

- *Race and sex distribution*—this condition is most evident in whites because of a lack of physiologic pigmentation in the oral mucosa of this population, but some dark-skinned individuals who smoke will have more prominent pigmentation in many oral sites. Females are affected more than males, which may be explained by the additive effects of estrogen in female smokers. Increases in estrogen levels observed during pregnancy and the use of birth control pills are linked to other hyperpigmentation conditions (e.g. melasma).
- *Age*—the incidence of smoker's melanosis increases with age, suggesting that the longer a person smokes, the more likely he or she will develop the condition. Some authors noticed a significant increase in gingival melanosis of children with parents who smoke.
- *Location*—smoker's melanosis has been mostly observed at the anterior mandibular gingiva; however, it can also be seen in other parts of the oral cavity. Other part involved is palate (Fig. 20-7), buccal and commissural mucosa, and inferior surface of tongue and lip mucosa.

Fig. 20-7: Heavy pigmentation seen in smoker melanosis.

- *Color*—smoker's melanosis has usually black-brown pigmentation. The prevalence of clinically visible oral melanin pigmentation is directly correlated with the number of cigarettes consumed per day. The consumption of 1-3 cigarettes/day elevates the prevalence of oral pigmented lesions from 3% among nonsmokers to 9%. When patients smoke more than 15 cigarettes/day, the prevalence increases to 31%.

Management

With cessation of the smoking, improvement is expected over the course of months to year. Smoker's melanosis, appears to be little significance. It may, however, potentially mask other lesions or may be cosmetically objectionable.

Differential Diagnosis

Other entities to consider in differential diagnosis are racial melanosis, melanosis due to medications, Peutz-Jegher's syndrome, Addison's disease and early melanoma. Smoker's melanosis is benign and not considered to be precancerous, but a biopsy may be indicated to rule out more serious conditions, in particular melanoma.

Melanoma

It is also called as *melanocarcinoma*. Melanoma is the malignant neoplasm of melanocytic origin that arises from a benign melanocytic lesion or *de novo* from melanocytes within otherwise normal skin or mucosa. It is the third most common cancer of skin but they may develop at any site where melanocytes is present.

Primary malignant melanoma of the oral mucosa is extremely rare tumor, representing 0.2 to 8% of all melanomas. Amelanotic malignant melanoma accounts for only 2.3% of all melanomas. Amelanotic malignant melanoma was defined as a tumor composed of nonpigmented melanocytes. However, another report, a tumor that lacks pigmentation clinically and has melanin pigmentation histopathologically is also included in this category. It is neoplasm of epidermal melanocytes.

Growth Phase

- *Radial growth phase*—radial growth phase is the initial phase of growth of the tumor. During this period, which may last many years, the neoplastic process is confined to the epidermis. In the early stages of melanoma development, the radial growth phase tends to predominate in lentigo-maligna melanoma, superficial spreading melanoma and acral lentiginous melanoma. In these lesions, the malignant melanocytes tend to spread horizontally through basal layer of the epidermis.

- *Vertical growth phase*—the vertical growth phase begins when neoplastic cells populate the underlying dermis. With nodular melanoma, the radial growth phase is very short or nonexistent and the vertical growth predominates.

Types

- *Based on clinical features*—the clinical appearance of the tumor is variable and may be divided into the following five types based on clinical features:
 - Pigmented nodular type
 - Nonpigmented nodular type
 - Pigmented macular type
 - Pigmented mixed type
 - Nonpigmented mixed type.
- *Clinicopathologic types*—four clinicopathologic (skin) types of melanoma have also been described.
 - *Superficial spreading melanoma*—superficial spreading melanoma is the most common form of melanoma. It accounts for 65-70% of cutaneous melanomas. It exists in a radial growth phase which has been called as premalignant melanosis or pagetoid melanoma in situ.
 - *Nodular melanoma*—nodular melanoma represents 13-15% of cutaneous melanomas. It apparently has no clinically recognizable radial growth phase, existing solely in a vertical growth phase.
 - *Lentigo-maligna melanoma*—it accounts for 5-10% of cutaneous melanomas. It exists in a radial growth phase which is known as lentigo-meligna or melanotic freckle of Hutchins. It predominantly occurs on sun exposed skin of elderly person. It is characterized by an extensive radial growth phase which may last up to 25 years before connective tissue invasion takes place.
 - *Acral lentiginous melanoma*—It is the most common form of melanoma in blacks and also the most common form of oral melanoma. It typically develops on the palms of the hands, soles, feet, subungual area and mucous membrane.
- *Superficial spreading melanoma*—it develops over several years into a sharply outlined, slightly elevated pigmented patch. The lesion presents as a tan, brown, black or admixed lesion on sun-exposed skin, especially in blacks. The most common sites of origin are the intercapsular area of males and the back of the legs of females.
- *Nodular melanoma*—clinically, it appears as darkly pigmented elevations on skin or mucous membrane. Nodular melanoma is usually a deeply pigmented exophytic lesion, although sometimes the melanoma cells are so poorly differentiated that they no longer can produce melanin, resulting in a nonpigmented amelanotic melanoma. This form of melanoma is invasive in nature from the start and metastasizes early. It has relatively poor prognosis.
- *Lentigo-maligna melanoma*—clinically, it appears as a flat, irregularly pigmented patch with an ill-defined margin. The appearance of nodularity with a lentigo-maligna signals the onset of the invasive or vertical growth phase.
- *Acral lentiginous melanoma*—it begins as a darkly pigmented, irregularly marginated macule which later develops a nodular invasive growth phase.

Oral Manifestations

- *Site*—oral melanoma exhibits definite predilection for the palate and maxillary gingiva.
- *Color and appearance*—an oral lesion typically begins as a brown to black macule with irregular borders. The macule extends laterally and a lobulated exophytic mass develops once the vertical growth is initiated.
- *Signs*—ulceration may develop early (**Fig. 20-8**) but many lesions are dark, lobulated, exophytic masses without ulceration at the time of diagnosis.

Fig. 20-8: Malignant melanoma showing ulceration and deep color pigmentation in the palate.

Clinical Features

- *Age and sex*—it can occur at any age group, but it is extremely rare in ages below 30. The age range for patient with oral melanoma is from 40-70 years, the average age being 55 years. It is more common in men.
- *Site*—the most frequent oral sites of occurrence are the palate and the maxillary gingiva, accounting for 80% of all melanomas. The most frequent head and neck site of occurrence of mucosal melanoma are the conjunctiva, followed by the upper respiratory tract and the oral cavity.

- *Symptoms*—pain is not a common feature except in ulcerated lesions and most lesions are relatively soft on palpation.

Radiological Features

- *Site*—in most cases, only the soft tissues are affected. Both primary and secondary malignant melanoma may rarely involve the bone of the jaws.
- *Moth eaten appearance*—some melanomas in the jaws, like those in other bones, may present radiographic appearances which are almost indistinguishable from osteomyelitis and patients have even been treated for this condition, until with the passage of time the error becomes apparent. Underlying or adjacent bone may show radiographic evidence of irregular or “moth-eaten” destruction.

Differential Diagnosis

- *Oral melanotic macule*—because of many clinical similarities exist between melanoma and its counterpart, the melanocytic nevus, an “ABCD” system of evaluation has been developed to help distinguish a melanoma clinically from a melanocytic nevus. **A**symmetry (because its uncontrolled growth pattern), **B**orders irregularity (often with notching), **C**olor variation (which varies from shades of brown to black, white, red and blue, depending upon amount and depth of melanin pigmentation) and **D**iameter often greater than 0.5 cm.
- *Melanotic neuroectodermal tumor of infancy*—occurs in infants.
- *Ecchymotic patch*—it disappears within few days.
- *Melanoplakia*—it is firm and occurs in infancy or puberty without change.
- *Intramucosal compound or blue nevus*—same as oral melanotic macule.
- *Pigmented fibroma*—histopathological diagnosis should be done.

Management

- *Surgical excision*—the treatment for cutaneous malignant melanoma is surgical excision. Although regional lymph node dissection is indicated when nodes are involved; prophylactic lymph node dissection is very controversial.
- *Radiotherapy*—radiotherapy is applied mainly on patients unable to undergo surgical treatment or as an adjuvant to surgery.
- *Preoperative chemotherapy*—preoperative chemotherapy is occasionally used to reduce the size of the melanoma and improve surgical management. The first line chemotherapeutic agent is dimethyltriazeno, imidazole carboxamide solely or in combination with vincristine

or dactinomycin. Other immunotherapeutic drugs that are occasionally used include interferon and cimetidine which when used together are believed to activate killer T-cells and inhibit suppressor T-cells resulting in the reduction of the size of the melanoma.

- *Intralesional injection*—Intralesional injection of interferon and polyvalent melanoma antigen vaccine.

Drug-induced Pigmentation

A number of medications may induce oral mucosal pigmentation. Direct deposition on oral surfaces, local accumulation after systemic absorption, stimulation of melanin related pathways, bacterial metabolism, alone or in combination, may result in oral pigmentations. Several antimalarial drugs are known to be capable of inducing intraoral melanin pigmentation. These drugs include: quinacrine, chloroquine, and hydroxychloroquine. Long term use may cause pigmentation of the oral mucosa.

Clinical Features

- *Color of pigmentation*—the pigmentation of the oral mucosa is described as slate-gray in color, bearing some resemblance to pigmentation caused by silver arsphenamine.
- *Location*—they are usually located on hard palate. Amodiaquine has been used to manage autoimmune disease and oral pigmentation occur in 10% of patient taking the drug on long term basis.
- *Minocycline pigmentation*—minocycline is a synthetic tetracycline that is commonly used in the treatment of acne vulgaris. Although tetracycline causes pigmentation of bones and teeth, minocycline alone is also responsible for soft tissue pigmentation. It is usually seen as brown melanin deposits on the hard palate, gingiva, mucous membranes, and the tongue.

Fig. 20-9: Drug induced pigmentation showing brown pigmentation.

- *Birth control pill pigmentation*—birth control pill can be associated with brown pigmentation of facial skin and perioral region.
- *Phenolphthalein*—these are associated with well circumscribed area of hyperpigmentation on skin and oral mucosa.

Differential Diagnosis

The diffuse distribution of pigment in drug induced lesion is similar to that seen in Addison's disease and, in the palate, to early superficial spreading melanoma. The history is, of course, of prime importance and biopsy is recommended.

Treatment

Withdrawal of the medication is recommended, although the pigmentation may persist for as long as one year after cessation of medication.

Physiologic Pigmentation

Oral pigmented lesions are usually caused by increased amount of melanin deposition. Physiologic pigmentation is one of these lesions and is defined as localized, symmetric hyperpigmentation which is commonly seen on attached gingiva.

Etiopathogenesis

- *Genetic*—physiologic pigmentation is probably genetically determined.
- *Mechanical, chemical and physical stimulation*—Dummett suggested, that degree of pigmentation is partially related to mechanical, chemical, and physical stimulation.
- *Activity of melanocytes*—in darker skinned people, oral pigmentation increases, but there is no difference in the number of melanocytes between fair-skinned and dark-skinned individuals. The variation is related to differences in the activity of melanocytes.
- *Age factors*—there is some controversy about the relationship between age and oral pigmentation. Steigmann and Amir et al stated that all kinds of oral pigmentation appear in young children. Prinz, on the other hand, claimed that physiologic pigmentation did not appear in children and was clinically visible only after puberty.

Clinical Features

This type of pigmentation is symmetric and persistent and does not alter normal architecture, such as gingival stippling.

- *Age distribution*—this pigmentation may be seen in patient at any age and is without gender predilection.

- *Location*—it may be found in any location, although the gingiva is the most commonly affected intra oral tissue. The most common pattern of physiologic pigmentation is the band of pigments on attached gingiva. Pigmentation may also be present on the buccal mucosa.
- *Color*—The color of the lesions ranges from brown to black to blue, depending on the amount of melanin production and the depth/location of the pigment.
- *Tongue pigmentation*—the tongue, however, is infrequently pigmented, but when this occurs, the pigments are characteristically localized at the tip of isolated groups of filiform papillae. Pigmentation was rarely found on the ventral surface of the tongue (**Figs 20.10 and 20.11**).
- *Post inflammatory pigmentation*—a related type of pigmentation, called postinflammatory pigmentation, is occasionally seen following mucosal reaction to injury.

Fig. 20-10: Physiologic pigmentation seen on tongue of patient.

Fig. 20-11: Physiologic pigmentation seen on tongue.

Differential Diagnosis

Clinical differential diagnosis would include smoking associated melanosis, the syndrome associated with oral

melanosis, Peutz-Jegher's syndrome and Addison's disease and melanoma. Although physiologic pigmentation is usually clinically diagnostic, biopsy may be justified if clinical features are atypical.

Treatment

- **Gingival surgery**—melanin pigmentation of the oral tissue does not present a medical problem, but some patient may complain of esthetic problem due to black gum. To overcome this issue, gingival surgery might be suggested.
- **Cryotherapy**—recently, cryotherapy is suggested for removal of such type of pigmentation has more advantages, like quickness, simplicity, lack of bleeding and scar compared to other method.

Post-inflammatory Pigmentation

Long-standing inflammatory mucosal diseases, particularly lichen planus (Figs 20-12 and 20-13), can cause mucosal pigmentation.

Etiology

The pathogenesis of post-inflammatory pigmentation remains unclear.

Fig. 20-12: Pigmented lichen planus present on buccal mucosa.

Clinical Features

This is seen more frequently in dark-skinned individuals. Clinically, multiple brown-black pigmented areas are noted adjacent to reticular or erosive lesions of lichen planus.

Cyanosis

- **Cause**—it is caused by substantial decrease in proportion of reduced hemoglobin to oxygenated hemoglobin in blood. It becomes apparent when reduced Hb is less than 5 g/100 ml.

Fig. 20-13: Pigmented lichen planus showing dark pigmentation.

- **Color**—generalized bluish cast to skin is seen in light skinned individuals. Generalized green may be caused by congenital heart defect, right ventricular failure and ventricular fibrillation and is associated with clubbing. Cold weather may cause peripheral cyanosis on lip.

HIV Oral Melanosis

- **Site**—buccal mucosa is most frequently affected followed by gingiva, palate and tongue.
- **Color**—it presents with diffuse, multifocal, macular brown pigmentation of the buccal mucosa.

Addison's Disease

It is also called as '*chronic adrenal insufficiency*'. Addison's disease is a hormonal disorder resulting from a severe or total deficiency of the hormones made in the adrenal cortex. Addison's disease is relatively uncommon condition estimated to occur in 1 in 100000 of the population. The oral manifestation has been documented, but it is unclear in how many cases oral pigmentation without systemic upset or skin pigmentation is the presenting feature. Clinically the disease is characterized by a bronzing of the skin and a pigmentation of the mucous membrane. Both oral and skin pigmentation are thought to be result from melanocytes-stimulating hormonal activity.

Etiology

- **Tuberculosis**—it was the leading cause of Addison's disease until the antibiotics were introduced that successfully treated TB.
- **Autoimmune disorders**—nowadays, the major cause is an autoimmune disorder in which the body's immune system makes antibodies which attack the cells of the adrenal cortex and slowly destroys them. This can take months to years.

- *Adrenocortical destruction*—bilateral adrenocortical destruction after tuberculosis or fungal infection and an idiopathic atrophy are the most frequent causes.
- *Others*—occasionally, bilateral tumor metastasis, leukemic infiltration, and amyloidosis of the adrenal cortex have been found to be responsible. Other less common causes include other chronic infections, cancer that has spread to the adrenals, CMV virus, and surgical removal of the adrenal glands. Whatever the cause, the loss of adrenal cortex results in deficiency in both glucocorticoids and minerlocorticoids.

Pathogenesis

It has been shown that ACTH and melanocytes stimulating hormone (MSH) are similar in structure, and ACTH is believed to have some degree of melanocytes stimulating activity. Normally, the pituitary gland produces ACTH which causes the adrenal cortex to produce glucocorticoids (such as hydrocortisone), which in turn are secreted into the circulation. When the glucocorticoids reach a certain concentration in the blood, they cause the anterior pituitary to cease production of the ACTH. In Addison's disease, however, the defective cortex is unable to produce much glucocorticoid, so this feedback mechanism is not activated and the pituitary continues to produce ACTH. As a result of the increased production of melanin changes, the color of the skin is a smoky tan or a chestnut brown.

Clinical Features

- *Signs and symptoms*—the signs and symptoms of Addison's disease are generally non-specific and include fatigue, weakness, weight loss, nausea, abdominal pain, diarrhea, and vomiting and mood disturbances. These symptoms steadily worsen over time due to the slowly progressive loss of cortisol and aldosterone production.
- *Skin signs*—The following skin signs may be indication of Addison's disease and should take prompt further investigations and appropriate tests.
 - Generalized darkening of the skin (hyperpigmentation) that may look like an inappropriate tan on a very ill person.
 - Hyperpigmentation is most evident on areas exposed to light, but also affects the body folds, sites of pressure and friction, and in the creases of palms and soles
 - Hyperpigmentation may also appear prominent on the nipples, armpits, genitals and gums (buccal mucosa).
 - Women may have loss of androgen-stimulated hair, such as pubic and underarm hair
- *Pigmentation*—pigmentation usually appears early and is one of the most prominent signs of the disease.

It may take one of the two forms, the more usual being a deep tanning of the skin and mucous membrane with heavier deposits of melanin over pressure points. The cheek is the most common site for this pigmentation in the oral mucosa. More infrequently, the increased melanocytic activity is expressed by the development of distinct brownish macule on the oral mucosa and the skin.

- *Color of pigmentation*—bluish black to pale brown or deep chocolate spreading over the buccal mucosa from the angle of the mouth (**Fig. 20-14**) or developing on the gingiva, tongue and lips.
- *Diagnosis*—if Addison's disease is suspected, tests measuring cortisol and aldosterone blood and urine levels must be performed to make a definitive diagnosis. The diagnosis of the Addison's disease is based on the clinical sign as well as on characteristic changes in the blood sodium and chloride levels.

Fig. 20-14: Bluish black pigmentation seen on buccal mucosa in Addison's disease.

Differential Diagnosis

- *Hyperpituitarism*—Addison's disease may be distinguished from hyperpituitarism by the use of urine test: levels of 17-ketosteroids in the urine are decreased in the former but elevated in latter condition. A history of silver ingestion identifies argyria.
- *Peutz-Jegher's syndrome, Albright's syndrome and von Recklinghausen's disease*—the macular type of discoloration that occasionally develops in place of the more generalized tanning might be mistaken for Peutz-Jegher's syndrome, Albright's syndrome, or von Recklinghausen's disease; however, the attending feature these individual syndromes should preclude any such confusion.

Management

It is done by adequate corticosteroid maintenance therapy provided by an average daily dose of 25 to 40 mg cortisone.

Peutz-Jegher's Syndrome

It is also called as *hereditary intestinal polyposis syndrome*. Peutz-Jegher's syndrome (PJS) is a rare familial disease first described by Peutz in 1921 and Jegher 1949 is an autosomal dominant disorder featuring gastrointestinal polyp and the pigmented macule on the lip and skin.

Etiology

To date, it has not been possible to determine the gene, although germline mutations have been detected on the LKB1 (STKI11) gene on chromosome 19p13.3. These are nonsense, frameshift and mis-sense mutations and all inactivate LKB1 gene which encodes a threonine kinase and behaves like a tumor suppressor gene.

Inactivation of this gene by germline mutations or loss of normal allele can result in hamartomatous polyps. Apart from the role of beta-catenin, adenomatous polyposis coli, K-ras and p-53 gene mutations have also been investigated.

The mucocutaneous pigmentations caused by melanin aggregation can be seen in 93% of patients even in infancy. They are generally located around the mouth, nose, cheek mucosa, hand, foot and sometimes perianal and genital areas.

Clinical Features

- **Age**—generally, it is of childhood onset with no sex predilection.
- **Intestinal polyps**—the major manifestation of PJS is the intestinal polyps that are found anywhere in the gastrointestinal tract, but most frequently in the small bowel especially in the jejunum. The number and the rate of growth of these polyps are variable.
- **Symptoms**—the polyp usually becomes symptomatic between the ages of 10 and 30, and may cause ulceration with bleeding, obstruction, diarrhea, and intussusceptions. Patient may be anemic from chronic blood loss. The polyps are usually benign, but malignant transformation may occur. Peutz-Jegher's syndrome has been accepted as a precancerous syndrome, with cancers being seen in 50% of patients.
- **Tuberous sclerosis**—tuberous sclerosis is a frequent neurologic problem in PJS patients and it is characterized by hamartomatous polyp, mental retardation, and epilepsy and adenoma sebaceum.
- **Pigmentation**—it is also characterized by multifocal macular melanin pigmentation in perioral location. It manifests itself as freckle like macules about the hands,

perioral skin (**Fig. 20-15**), and intraorally to include the gingiva, buccal, and labial mucosa. Pigmented spots are 1 to 10 mm in diameter and asymptomatic.

- **Sites of oral pigmentation**—pigmented spots are particularly found on the lower lip and buccal mucosa but rarely on the upper lip, tongue, palate, and gingiva. The pigmented macules appear at birth or in early childhood and may gradually disappear from the skin but not from the buccal mucosa. PJS is easily distinguished from freckles which are usually on sun exposed area and from generalized lentigines which are widely scattered. The pigmentation of the PJS, on the other hand, is acral, perioral, and oral.
- **Color of pigmentation**—there are *bluish-black* macules on skin. Orally it presented as brownish macules.
- **Clinical significance**—the lesion is of clinical significance only as a diagnostic clue to the more serious intestinal problem. Any child with recurrent unexplained abdominal pain should be examined for the cutaneous and mucosal pigmentation of PJC. It is recommended that any patient presenting with ileus attacks and anemia should be investigated for polyps and the mucocutaneous pigmentation of Peutz-Jeghers syndrome. In addition, patients in whom this syndrome is diagnosed should be evaluated for cancer and family screening should be considered.

Fig. 20-15: Macular pigmentation seen in Peutz-Jegher's syndrome.

Management

Referral to a gastroenterologist is recommended. No treatment is required for oral lesions.

Neurofibromatosis

It is also called as *Von Recklinghausen's disease*. It is transmitted as autosomal dominant trait. In it, multiple neurofibromas of the skin along with brown spots are seen.

Clinical Features

- **Triad**—clinical triad consists of areas of pigmentation (**Fig. 20-16**) sessile or pedunculated tumors of skin and mucous membrane and tumors of nerves.
- **Tumors**—tumors are of plexiform variety and thus are soft, smooth, fluctuant, flesh colored and nodular or pedunculated. Multiple cavernous neurofibroma and auxiliary folding can be seen.
- **Café-au-lait spots**—are cutaneous lesions which are characteristic of the disease.

Fig. 20-16: Area of pigmentation seen with swelling on the face.

Oral Manifestation

- **Site**—areas of melanin pigmentation are seen on oral mucosa with lips being the common site of involvement.
- **Intraoral growth**—there is presence of intraoral growth inside the oral cavity (**Fig. 20-17**).

Fig. 20-17: Intraoral sessile growth seen in patient of neurofibromatosis.

Radiographic Features

- **Appearance of intrinsic bone tumor**—in intrinsic bone tumors, there are actual tumor masses within the bone which appear as central cyst like radiolucency, subperiosteal bone blister and irregular areas of bone destruction.
- **Appearance of extrinsic bone tumor**—extrinsic bone tumor produces an area of bone destruction or prevents normal development of contour of the bone. Tumor which affects only the superficial portion of the bone may result in the formation of depression and elevation, pits and superficial cavities.

Differential Diagnosis

- **Basal cell syndrome**—tumor is restricted to skin of face, neck and chest. Pigmentation is not feature.
- **Gardener's syndrome**—pigmentation is not seen.

Management

- **Surgical excision**—surgical excision of individual lesion.

Albright's Syndrome

- A type of fibrous dysplasia involving all the bones in the skeleton accompanied by the lesions of the skin and endocrine disturbances of varying types.
- Skin lesions are irregularly pigmented melanotic spots described as café-au-lait spots due to their light brown color.
- It is more common on lips.

Differential Diagnosis

- **Addison's disease**—discrete macules are seen in adrenal insufficiency.
- **Peutz-Jegher's syndrome**—pigmented macules on skin restricted to areas surrounding the body orifices, on finger and both.

Hyperfunction of the Pituitary Gland

There is increased secretion of ACTH and MSH thus causing increase in melanization rate causing pigmentation.

Pregnancy and Female Sex Hormones

Increased ACTH levels during pregnancy is the cause of abnormal pigmentation of circumoral tissues and nipples are seen in the third trimester of pregnancy, this is called as *chloasma grandarum*. This also occurs with use of oral contraceptive containing large doses of sex hormones. In all these, functions of pituitary gland are increased causing pigmentation.

Occasionally, it is accompanied by diffuse browning of oral mucosa and slowly disappears after delivery.

Brown Heme Associated Lesion

Ecchymoses and Petechiae

They are purpuric submucosal and subcutaneous hemorrhages (Fig. 20-18). Petechiae are minute pinpoint hemorrhages while ecchymosis is larger than 2 cm in diameter.

Fig. 20-18: Petechiae seen on tongue due to trauma.

Clinical Features

- **Site**—common on lips and face.
- **Causes**—it occurs immediately following traumatic event and erythrocyte extravasation into submucosa.
- **Color**—it appears as bright red macule (Fig. 20-19) or swelling, if hematoma is formed. After hemoglobin is degraded to hemosiderin, lesion assumes brown color. It does not blanch on pressure.
- Fluctuant swelling, as hemorrhage is slow and no sufficient blood to pool.

Differential Diagnosis

- *Amalgam tattoo, oral melanotic macule, junctional nevus, melanoma and telangiectasia in Rendu-Osler-Weber syndrome*—in all of the above, history of recent trauma, change from bluish brown to green to yellow and then disappearing lesion within 4 to 5 days indicate petechiae.
- *Trauma from fellatio*—disappear in few days after passing through blue to green to yellow color changes to be taken. Careful history should be taken.
- *Trauma from vomiting and coughing*—broad linear red or bluish bruise.

Fig. 20-19: Leg macule seen as bright red macule.

- *Infectious mononucleosis*—malaise, enlarged nodes in neck, positive monospot test followed by positive Paul Bunnell heterophil test.
- *Hemostatic disease*—complete blood examination is done.

Management

- Surgery, after detection of disease.

Hemochromatosis or Bronze Diabetes

- **Tetrad**—it is tetrad of liver cirrhosis, diabetes, cardiac failure and bronze skin.
- **Causes**—Bronze diabetes (Hemochromatosis) is a disorder in which excess iron is deposited in the body and result in eventual sclerosis and dysfunction of the tissue and organ involved. The cause of tanning in hemochromatosis, like that in Addison's disease, is an increased melanin production and not the deposition of hemosiderin in the skin. This increased production, as in Addison's disease result from the high level of ACTH that accompany the destruction of the adrenal cortex by the heavy iron deposits.
- **Site**—Involved organs are liver, skin, pancreas and adrenal gland.
- **Sex distribution**—80% occurs in men
- **Color**—tanning occurs due to increased melanin production. Blue gray color of skin especially over genitals, face and arms.
- **Intraoral features**—in this, diffuse black brown pigmentation is seen at the junction of hard and soft palate (Fig. 20-20).

Carotenemia

Causes—chronic excessive levels of carotene pigments due to long and continuous consumption of food containing

Fig. 20-20: Black brown pigmentation seen at the junction of hard and soft palate in hemochromatosis.

carotene such as carrots, sweet potatoes and egg. An orange to yellow pigmentation of skin and oral mucosa occurs. Color change is more intense on palm, soles and areas of soft palate.

Jaundice

Yellow or green discoloration of the skin and mucous membrane with bile pigments. Oral mucosa presents a yellowish discoloration. Tongue is heavily coated.

Hematoma

Hematoma is a localized collection of blood, usually clotted, in a tissue or organ. Lingual hematoma has been documented as a result of maxillofacial trauma causing tongue laceration, post-extraction complication, severe hypertension, unusual complications of anticoagulant therapy, and surgical implant placement. Although not recorded in the dental literature, periodontal flap procedures may also affect hematoma formation. While a relatively uncommon sequelae of surgical therapy, the broad spectrum of events resulting in hematoma necessitates the dental practitioner's familiarity with its diagnosis and treatment. The floor of the mouth hematoma can be more problematic because of the facial planes are involved and the anatomical structures at this site.

Etiology

A hematoma is generally the result of hemorrhage, or, more specifically, internal bleeding. Hematoma exists as bruises (ecchymoses), but can also develop in organs. Injuries to the facial bones and jaw can produce bleeding not only in the tongue, but also in the adjacent facial structures. Excessively traumatized capillary beds extravasate blood

into the perivascular connective tissue. Poor circulation at the site allows pooling of blood, prostaglandin release, and a more profound inflammatory reaction.

Clinical Features

Mucosal hematoma bruise result from vascular severance result from trauma (**Fig. 20-21**). They are brown or blue and may be macular or swollen. Because the blood is intraluminal but extravasated, hematoma does not blanch on pressure. The early hematoma is fluctuant, rubbery, and discrete in outline, and the overlying mucosa is readily movable. The temperature of the overlying mucosa may be slightly elevated. When it is superficial, it appears as an elevated bluish swelling in the mucosa. Digital pressure on the surface may induce a stinging sensation as the pressure on the contained pool of the blood causes further separation of the tissue. A hematoma is usually completely clotted within 24 hours and then becomes a hard black, painless mass. If the hematoma is superficially located, changes from black to blue to green to yellow may be observed during the following days. If hematoma becomes infected, it is painful. Although the clot is initially firm, if the infection is a pyogenic type, the firm clot softens and become fluctuant as pus accumulates.

Hematoma involving the tongue frequently affect swallowing and speech. As the hematoma enlarges, or extends into the surrounding tissue below the tongue, obstruction of the airway occurs.

Fig. 20-21: Hematoma seen on tongue due to trauma.

Differential Diagnosis

A history of traumatic incident like accident, surgery, or administration of local anesthetic can almost always be elicited from the patient and is useful in establishing the diagnosis of early hematoma. Hematomas are the result of trauma may be confused clinically with hemorrhagic mucocoele, tattoo, hemangioma or varix, nevus, melanoma.

Ecchymosis is identical, yet in blood dyscrasia, trauma is minor and the lesions are usually multifocal

Treatment

Hematomas that occur intracranial require immediate specialized medical attention. The hematoma is usually self-limiting in size because the increasing pressure of the blood in the tissue equalizes with the hydrostatic pressure in the injured vessel and thus terminates the extravasations. If a large arteriole is damaged, however, a pressure bandage may be placed over the accessible area to control the hemorrhage and limit the expansion of the hematoma. Occasionally, it may be feasible to evacuate an expanding or painful hematoma with an aspirating syringe and then apply a pressure bandage to prevent its re-formation. If the patient appears to be developing a problem with respiration the patient should be hospitalized and proper measure instituted to establish and maintain the airway. Antibiotic may be given to prevent the secondary infection.

For contusions (bruises), treatment consists of initially applying ice or cold packs a few times a day, to produce vasoconstriction (a reduction in arterial blood flow) which helps to decrease hemorrhage (bleeding) and edema (swelling). A suspected hematoma should be observed for 2-week period. Failure to resolve indicate the clinical impression was incorrect and biopsy should be performed. Any hematoma observed without significant provocation or trauma should arouse suspicion of purpura associated with blood dyscrasia.

Exogenous Pigmentation

It is defined as a pigmentation which arises as a result of introduction of metal/drugs into the body via mucous membrane, intestinal tract and skin.

Classification

- *Accidental pigmentation*—this type of pigmentation occurs due to accidental implantation of material in the gingival tissue.
- *Iatrogenic pigmentation*—this occurs due to dental procedure.
- *Heavy metal pigmentation*—this occurs due to ingestion of metal in the body.

Accidental Pigmentation

Foreign substances are embedded in the gingival tissue. It may be due to:

- *Accident during childhood*—for example, if one falls on road, some particles of the road surface gets embedded in gingiva and if not removed, may cause discoloration.
- *Charcoal tooth powder*—charcoal containing tooth powder also produces black permanent discoloration.
- *Graphite tattoos*—pencil points are occasionally broken off in gingival tissue and if not completely removed, may cause permanent discoloration. It tends to occur on the palate. The lesions are usually macular, focal, and gray or black. Since the traumatic event usually occurs in classrooms during grade school, many patients may not recall the injury. Pigment does not blanch on pressure. History will confirm the diagnosis of graphite tattoo.

Iatrogenic Pigmentation

Amalgam Tattoo

It is also called as *localized argyrosis*. Dental amalgam tattoos are relatively common intraoral pigmented lesions, with an estimated incidence of 8%. It is characterized by the deposit of restorative debris composed of a mixture of silver (Ag), mercury (Hg), tin (Sn), zinc (Zn), and copper (Cu) in subepithelial connective tissue.

Etiology

- *Restorative work*—it may be condensed in the abraded gingiva during routine amalgam restorative work.
- *Removal of old filling*—it may enter the mucosa lacerated by rotary instruments during removal of old amalgam fillings or crown and bridge preparations of teeth with large amalgam restorations.
- *During extraction*—broken pieces may be introduced into the socket or beneath the periosteum during extraction of the teeth.
- *Retrograde amalgam filling*—particles may enter the surgical cut during root canal treatment with retrograde amalgam filling. There may be chances of corrosion of retrograde amalgam filling.

Clinical Features

- *Site*—the most common sites are on gingiva and alveolar mucosa with mandibular region being affected more commonly than maxillary region.
- *Age and sex distribution*—it can occur at any age but it is rarely seen below the 12 years as amalgam restorations are not used before the age of 12 years. Females are affected more commonly than males in ratio of 1.8:1.
- *Appearance*—it is described as a flat macule or sometimes slightly raised lesion with margins being well defined or diffuse in other.
- *Color*—pigmentation is blue black in color (Fig. 20-22). It may gradually increase in size.

Fig. 20-22: Blue black pigmentation seen adjacent to amalgam restoration in amalgam tattoo (Courtesy Dr Chole).

Radiological Features

- It will demonstrate the presence of the metal.

Differential Diagnosis

- *Superficial hemangioma*—it blanches on pressure while amalgam tattoo does not.
- *Nevus and melanoma*—rare in oral cavity. It has brown color as compared to tattoo which has blue black color.

Management

- *Surgical excision*—once present, the amalgam tattoo remains indefinitely, and occasional lesions slowly enlarge over time, presumably as amalgam-laden histiocytes try to move the material out of the local site. No treatment is necessary, but excisional biopsy is often performed in order to rule out melanoma or another pigmented lesion. Lesions visible on radiographs are usually not biopsied and those occurring on the visible vermillion border of the lips are usually removed for aesthetic reasons. There is no malignant potential for this lesion.

Pigmentation due to Drugs and Metals

Bismuthism

It is systemic metallic intoxication due to bismuth compound.

Etiopathogenesis

- *Medicinal use*—nowadays, medicinal use of bismuth is rare. In the past, it is used in the treatment of venereal disease. Many proprietary drugs contain bismuth salt and bismuth containing pastes may result in bismuth pigmentation.
- *Occupational exposure*—person working in bismuth factory can cause bismuth intoxication.
- *Mechanism*—pigmentation is produced by the action of hydrogen sulfide on the bismuth compound. The hydrogen sulfide is formed through bacterial degradation of organic material of food retention.

Clinical Features

- *Symptoms*—vague gastrointestinal tract disturbances, nausea, bloody diarrhea, *bismuth gripe* and jaundice.
- *Bismuth line*—sometimes in the long bone, white bands of increased density appear in the ends of the diaphyses immediately adjacent to the epiphyseal lines. This is called as 'bismuth line'.

Oral Manifestations

- *Symptoms*—patients often complain of a metallic taste, increase salivation with burning sensation in the oral cavity
- *Ulcerative gingivostomatitis*—it is very common occurrence in bismuth poisoning.
- *Sign*—large, extremely painful, shallow ulcerations are seen at times on the cheek mucosa in molar region. Regional lymphadenopathy may be present.
- *Tongue*—tongue is frequently enlarged and sore.
- *Bismuth line*—'blue black' bismuth line appears to be well demarcated to eye on gingival papillae. Blue black bismuth sulfide granules formed by action of H_2S produced by action of bacteria on organic material remaining in areas of poor oral hygiene.
- *Paper test*—it will indicate whether the pigmentation is actually in gingival tissue. If the pigmentation persists, when small piece of white paper is inserted in the gingival sulcus, the presence of pigmented area is verified.

Management

- *Removal of cause*—Stoppage of use of bismuth.
- *Oral hygiene maintenance*—dentist should establish and maintain oral hygiene of the patient.
- *Topical anesthetics*—management of painful ulcerative lesions should be done by topical application of lignocaine hydrochloride gel.

Plumbism or Lead Poisoning

It occurs due to lead poisoning.

Etiopathogenesis

- **Lead based paint**—lead is present in paint and children can ingest chips of paint. While renovation and sanding, lead may appear in dust resulting in lead intoxication.
- **Lead in illicit alcohol**—moonshine an illicit alcoholic beverage distilled in car radiators has been shown to cause acute lead poisoning.
- **Lead in gasoline**—use of tetraethyl lead, an antiknock compound in gasoline (petrol), has introduced a new source of lead to the public. Removal of lead from gasoline is nowadays carried out and you can get unleaded petrol.
- **Occupational exposure**—excessive absorption of the lead from automobile exhaust and dust can lead to occupational exposure of lead.
- **Mechanism**—absorption of lead from alimentary tract, lungs and gut → modulated by vitamin D and calcium status of the individual → lead is taken up by circulating erythrocytes and bound to reactive sulfhydryl group of proteins → from the circulation, lead is transferred to all the soft tissues and in high concentration, it will inhibit metabolic pathways → in the red cells, lead inhibits enzymes associated with hemoglobin synthesis, hence abnormal activity of the enzymes occurs.

Clinical Features

- **Nervous system**—lead has high affinity for cells in central as well as peripheral systems. In acute poisoning, demyelination and axon degeneration occurs. Lead encephalopathy, cerebral palsy, mental retardation, seizures, wrist or foot drop and fatigue can occur.
- **Gastrointestinal tract**—there may be serious gastrointestinal disturbances like nausea, constipation, vomiting, and colic.
- **Bone**—when incorporated in the bone, it can interfere with cellular metabolism and changes are seen in the rate of bone resorption and apposition.

Oral Manifestations

- **Symptoms**—there is a metallic taste which is accompanied by excessive salivation and dysphagia.
- **Burtonian line**—when exposure to lead is very high and oral hygiene is very poor, a line known as 'burtonian line' is seen which is *gray black* in color (**Fig. 20-23**) and is present along the gingival margin. Lead line is more diffuse than bismuth line.
- **Signs**—there is pallor of lip, poor muscle tone and the face appear *ashen* in color because of associated anemia. Tremor of tongue may present on thrusting.
- **Parotid gland**—there is bilateral parotid gland hypertrophy.

Fig. 20-23: Plumbism showing gray black line on the gingiva.

Radiological Features

- **Lead line**—lead line can be seen in the long bones and skull. It represents deranged calcium metabolism that results from the activity of lead on osteoclastic activity and calcium resorption.

Management

- **Chelating agents**—lead can be removed from body by using a chelating agent such EDTA (calcium disodium ethylenediaminetetraacetate). But nowadays, other chelating agents DMSA (2, 3-dimercapto-succinic acid) and DMPS (2, 3-dimercaptopropane-1-sulfonate) are used.

Mercurialism

It is also called '*Pink disease*', '*Swift's disease*', '*Dermatopolyneuritis*', and '*Acrodynia*'. It is an uncommon disease caused due to a mercurial toxicity reaction, either actual mercury poisoning or, more likely, an idiosyncrasy to the metal.

Etiology

- **Medicinal use**—mercury can be used in teething powder, cathartic agents and antihelminthics preparation.
- **Mercury in dental amalgam**—improper use of dental amalgam alloy which contain mercury can also cause mercurialism. But there is no documented literature on the mercury toxicity occurring due to dental amalgam.
- **Mercury in paint**—mercury hazards exist in paints containing mercurial salts such as phenylmercuric propionate.
- **Mercurial diuretics**—prolonged administration of mercurial diuretics can also result in mercurialism.

- *Night cream*—frequent use of night cream containing inorganic salts may produce distinctive discoloration.
- *Occupational*—mercurial fumes which are produced industrially also result in bone changes in the jaws, if inhaled in quantity.

Clinical Features

- *Age*—it occurs most frequently in young infants before the age of 2 years although children can be occasionally affected up to age of five years or six years.
- *Gastrointestinal symptoms*—intestinal colic and diarrhea. There is also pharyngitis, dysphagia, nausea, abdominal pain.
- *Nervous symptoms*—long continued exposure to mercury vapor can result in permanent neurological changes. Headache, insomnia, tremors of fingers and tongue and mental depression.
- *Renal symptoms*—severe intoxication and it can be the cause of death.
- *Color of pigmentation*—hands, feet, nose and cheeks assume pink color.
- *Hair and nails*—the nails are shed at the same time with teeth lost prematurely and alopecia is also present. The children will frequently tear their hair out in patches.
- *Raw beef appearance*—the skin of hands, feet, nose, ears and cheek becomes clammy red or pink and has a cold clammy feeling. The appearance is described as resembling raw beef.
- *Skin*—the skin over the affected area peels frequently during the course of the disease. The patients also have maculopapular rash which is extremely pruritic.
- *Others finding*—severe sweating, extreme irritability, photophobia with lacrimation, insomnia, muscular weakness, tachycardia and hypertension.

Oral Manifestations

- *Symptoms*—there is marked increase in inflow of ropy viscid saliva. This will cause dribbling. Patient may experience itching sensation and metallic taste in the oral cavity. Mastication is difficult due to pain.
- *Gingiva*—the gingiva becomes extremely sensitive or painful and it may exhibit ulceration. The gingiva may become blue gray to black in color
- *Ulcerative stomatitis*—oral mucosal ulceration occurs and spreads to the palate, throat and pharynx.
- *Salivary gland and lymph nodes*—salivary glands and lymph nodes may be swollen.
- *Tongue*—tongue is enlarged, painful and ulcerated. Tongue tremors may be present.
- *Lips*—lips are dry, cracked and swollen.
- *Teeth*—sound teeth may exfoliate and one or more teeth may be found on bed in the morning as patients awake.

The reason for it is that there is marked periostitis with loosening of the teeth which may lead to exfoliation of teeth. In many cases children extract his own teeth with the help of his finger.

- *Bone*—the loss of teeth sometimes followed by necrosis of bone and there may be sequestrum formation.
- *Bruxism*—bruxism is a common finding.

Radiographic Features

- *Appearance*—changes occurring in the jaw are similar to the changes seen in osteomyelitis except that changes may be localized at first and gradually extend until large portion of bone involved.
- *Irregular bone destruction*—there is irregular area of bone destruction with loss of cortex of the follicle of the affected tooth.

Management

- *Supportive measure*—bed rest and suitable dietary regimen should be adjusted for renal damage.
- *Control of salivary flow*—atropine or belladonna can be prescribed to lessen the salivary flow.
- *Chelating agents*—administration of chelating agents BAL- British anti-lewisite (2,3-dimercaptopropanol) is recommended. But nowadays, as side effect of BAL is more, another chelating agents DMSA (2,3-dimercaptosuccinic acid) and DMPS (2,3-dimercaptopropane-1-sulfonate).

Argyria or Silver Poisoning

It is also called as 'argyrosis' which occurs due to chronic exposure to silver compound.

Etiology

- *Medicinal use*—it occurs from local and systemic absorption of silver compounds. Silver is used in nasal drops or sprays. Silver-arsphenamine injection used to treat syphilis. Silver is also used in some cases of apthous ulcer.
- *Photographic films*—chewing pieces of photographic films over an extended period can also result in argyria.
- *Occupational exposure*—industrial exposure is also one of main cause of silver poisoning.
- *Mechanism*—silver is disseminated in the body and it accumulates as subepithelial deposits in the skin.

Clinical Features

- *Site*—exposed body surfaces, nail-beds are commonly involved.

- **Skin**—skin is slate gray, violet or cyanotic and in marked cases, there is even suggestion of metallic luster.
- **Nails**—nails are also deeply pigmented.

Oral Manifestations

- **Site**—pigmentation is distributed diffusely throughout the gingival and mucosal tissue.
- **Color of gingiva**—there is *slate blue silver* line along the gingival margins.
- **Oral mucosa**—oral mucosa exhibits a diffuse bluish black discoloration.

Management

- **Removal of cause**—source of contact should be eliminated.

Arsenism

It occurs due to arsenic poisoning.

Etiology

- **Industrial exposure**—arsenic exposure from industrial use can lead to arsenic poisoning.
- **Medicinal use**—arsenic is used to treat asthma and dermatose such as psoriasis.

Clinical Features

- **Symptoms**—chronic gastritis and colitis, keratosis of palms of the hand and soles of feet.
- **Hyperpigmentation**—diffuse macular hyperpigmentation is seen on the skin of the patient. This occurs due to increase in melanin production.
- **Arsenical keratosis**—these are the premalignant skin lesion which can occur in arsenic poisoning.
- **Other complication**—patient can also notice palmar and plantar hyperkeratosis, basal cell carcinoma and cutaneous squamous cell carcinoma.

Oral Manifestations

- **Symptoms**—oral tissues are extremely painful and patient may complain of excessive salivation.
- **Severe gingivitis**—gingiva become intensely inflamed.
- **Necrotizing ulcerative stomatitis**—local contact with arsenic trioxide often produces ulceration which can become necrotic.
- **Dorsal hyperkeratosis of tongue**—this occurs in patient in past, who has taken arsenic for syphilis treatment.
- **Color of pigmentation**—tissues are deep red in color.

Management

- **Anesthetic ointment**—surface anesthetic ointment or rinses such as lidocaine or dyclonine solution can be given to control pain occurred due to salivation.

- **Chelating agents**—BAL (2,3-dimercaptopropanol) is used initially for the treatment of arsenic poisoning. But nowadays as side effect of BAL is more another chelating agents DMSA (2,3-dimercapto-succinic acid) and DMPS (2,3-dimercaptopropane-1-sulfonate).

Auric Stomatitis or Gold Poisoning

Auric stomatitis occurs due to gold poisoning.

Etiology

- **Medicinal use**—gold is useful for the treatment of rheumatoid arthritis, lupus erythematosus and leprosy.

Clinical Features

- **Dermatitis**—it is the most common complaint of patient. Patient may notice pruritus before the lesion of dermatitis occurs.
- **Other features**—purpura, alopecia, loss of nails and malignant neutropenia can also occur.
- **Chrysiasis**—slate blue discoloration of skin occur in gold poisoning. This is called as chrysiasis.

Oral Manifestation

- **Site**—it includes buccal mucosa, lateral border of tongue, palate and pharynx.
- **Symptoms**—patient gets metallic test in the oral cavity before the development of stomatitis.
- **Stomatitis**—it is the most common complaint of the patient who is receiving gold therapy.
- **Sign**—vesiculation and ulcerations of the oral mucosa.

Management

- **Removal of cause**—patient should be advised to discontinue of gold therapy.
- **Alkaline mouth wash**—this should be prescribed to treat oral stomatitis.

Pigmentation due to Copper, Chromium, Zinc

- **Copper**—it results due to chronic intake of copper salts which may be associated with development of anemia. There is bluish green line on gingiva and teeth, which is called as 'Clapton line'. Tooth discoloration is permanent because of etching of enamel.
- **Chromium**—chrome platers are exposed to fine spray of chromic acid that is irritating and corrosive to the mucous membrane of the nose and throat. Patient experience burning, soreness, and dryness of mouth associated with swelling of tongue. There is painful ulcerations of the nasal septum which results in perforation. Teeth may become etched and show persistence *deep orange color*.

- **Zinc**—it is an occupational hazard in molten brass workers and electric arc worker. It is associated with chills, fever, sweating and rapid pulse. Nausea, vomiting, dryness, burning of the upper respiratory tract and metallic taste are also associated. In oral cavity, there is congestion and suppuration of the gingival tissues. There are also painful submaxillary lymph nodes and salivary gland involvement also occur. There is *bluish gray line* present on the gingiva.

Summary

Pigmentation is the both normal and abnormal discoloration of oral mucous membrane. Pigmentation has multifactorial etiology. Most of the pigmentation is physiologic but sometimes it can be a precursor of severe diseases. Melanin pigment irregularities and color changes of the oral tissues could provide significant diagnostic evidence of both local and systemic disease. Evaluation of a patient presenting with a pigmented lesion should include a full medical and dental history, extraoral and intraoral examinations, and laboratory tests. The history should include the onset and duration of the lesion, the presence of associated skin hyperpigmentation, the presence of systemic signs and symptoms (e.g. malaise, fatigue, weight loss), use of prescription and nonprescription medications, and smoking habits. Pigmented lesions on the face, perioral skin and lips should be noted. The number, distribution, size, shape and color of intraoral pigmented lesions should be assessed. In general, benign pigmented lesions show regular borders and are small, symmetric and uniform in color. They may be either flat or slightly elevated. In contrast, irregular borders, color variation, and surface ulceration suggest malignancy. Clinical tests such as diascopy, radiography and laboratory investigations such as blood tests can be used to confirm a clinical impression and reach a definitive diagnosis. However, because it is not always possible to distinguish between a benign pigmented lesion and an early melanoma on the basis of clinical features alone, biopsy is usually recommended for focal oral pigmented lesions that cannot be explained by local factors. The recognition, identification, and clinical assessment of pigmentation is of great importance because of the possible risk of serious systemic disease, such as melanoma, various syndromes, and the side effects of drugs.

Hypopigmentation in Oral Cavity

Albinism

The word “albinism” refers to a group of inherited conditions. People with albinism have little or no pigment

in their eyes, skin, or hair. They have inherited altered genes that do not make the usual amounts of a pigment called melanin.

Albinism affects people from all races. Most children with albinism are born to parents who have normal hair and eye color for their ethnic backgrounds. Sometimes people do not recognize that they have albinism.

People with albinism are at risk of isolation because the condition is often misunderstood. Social stigmatization can occur, especially within communities of color, where the race or paternity of a person with albinism may be questioned.

Clinical Features

- **Vision problems**—albinism is associated with vision problems and has low vision. Vision problems in albinism result from abnormal development of the retina and abnormal patterns of nerve connections between the eye and the brain. It is the presence of these eye problems that define the diagnosis of albinism. Therefore, the main test for albinism is simply an eye examination.
- **Skin problems**—while most people with albinism are fair in complexion (**Fig. 20-24**). Skin or hair color is not diagnostic of albinism. People with many types of albinism need to take precautions to avoid damage to the skin caused by the sun such as wearing sunscreen lotions, hats and sun-protective clothing. In less pigmented types of albinism, hair and skin are cream-colored.

Fig. 20-24: Hand of the patient with albinism showing depigmented area.

- **Facial skin**—facial skin show depigmented area (**Fig. 20-25**).
- **Skin cancer**—those who do not use skin protection may develop life-threatening skin cancers.

Fig. 20-25: Hypopigmented region of face in albinism.

Management

- **Skin protection**—use appropriate skin protection, such as sunscreen lotions, higher and opaque clothing, and people with albinism can enjoy outdoor activities even in summer.
- **Avoid social stigma**—families and schools must make an effort not to exclude children with albinism from group activities.

Vitiligo

It is localized type of hypopigmentation. It is progressive symmetric areas of complete pigment loss. It is most commonly seen area around mouth (Fig. 20-26). lip, nose, nipples and anus. Color of pigmentation is chalk white. Management is done by topical glucocorticoids, PUVA therapy.

Fig. 20-26: Hypopigmentation in oral cavity may occur localize type of vitiligo.

Introduction

Dental caries is a microbial disease of the calcified tissues of the teeth, characterized by demineralization of the inorganic portion and destruction of the organic substance of the tooth. It is one of the most common infectious diseases affecting the human race. Cariogenic plaque contains 2×10^8 bacteria per milligram weight and pH of 5.5 is critical threshold for the demineralization. The initial lesion appears as opaque white or brown spot beneath the plaque layer. As the caries process results in demineralization, the affected area of the tooth appears more radiolucent than unaffected area. Carious area attenuates less radiation than intact tooth substance so that the area of the film on which remnant beam from the demineralized area falls, it receives higher exposure and thus appears more darker on the processed radiograph.

The disease process begins with the concentration of *Streptococcus mutans* at specified tooth surfaces and lead to white spot formation or even cavitations. The development of dental caries is a dynamic process of demineralization of the dental hard tissues by the products of bacterial metabolism, alternating with periods of remineralization.

Etiology

- *Dietary factor*—carbohydrates with types like monosaccharides, disaccharides or polysaccharides and the amount consumed and whether it is between meals.
- *Microorganisms*—acidogenic *Streptococcus mutans* and *Actinomyces viscosus*.
- *Systemic factors*—hereditary, pregnancy and lactation factors have been suggested as etiological factors for dental caries.
- *Host factor*—poor oral hygiene and improper brushing technique can lead to dental caries.

- *Immunological factor*—the functional role of circulating antibodies as protective agents against tooth decay has been demonstrated in non-human primates.

Pathogenesis

- *Fermentation of oral microorganism*—whenever carbohydrate is consumed, oral microorganisms rapidly begin fermentation producing organic acids like lactic acid, acetic acid and formic acid. This leads to fall in pH of the oral fluids.
- *Demineralization*—these organic acid attack the tooth structure, resulting in loss of tooth minerals specially calcium and phosphate ions, which leach out from hydroxyapatite. This process is known as 'demineralization'.
- *Remineralization*—after a period of 30 minutes, due to salivary buffering by bicarbonate ions and ammonia production from salivary proteins, there is an increase in pH of the oral fluids. The acid is neutralized and the condition now favors precipitation of calcium and phosphate ions into tooth surface. This process is called as 'remineralization' and is hastened if fluoride is present in a small amount in either plaque fluid or saliva.
- *Further demineralization*—the microorganism which is of primary concern in the pathology of dental caries is *Streptococcus mutans*. It forms insoluble, sticky extracellular polysaccharides which help in further colonization and increases the contact of the acids with the tooth structure, leading to further demineralization which ultimately leads to cavitations.
- *Formation of caries*—the balance between the caries causing and caries protective factors is very delicate. It is only when repeated attacks of demineralization occur that there is a net loss of minerals from tooth and caries results. The surface layer of enamel overlying the lesion

remains intact and the demineralization occurring is primarily subsurface in location. Once this happens, the process gradually extends deeper, involving enamel and subsequently the dentin and pulp.

Theories of Cariogenesis

Proteolytic Theory

Proteolysis can play a role in dental caries process, particularly in lesions that develop on exposed root surface.

Proteolysis Chelation Theory

It is postulated that oral bacteria attack organic component of enamel and that their breakdown products have chelating ability and this dissolves the tooth minerals.

Chelation is the process involving the complexing of a metallic ion to a complex substance through a coordinate covalent bond which results in a highly stable, poorly dissociated or weakly ionized compound.

Acidogenic Theory

It is generally agreed that dental caries is caused by acid resulting from action of microorganisms on carbohydrates. It is characterized by decalcification of the inorganic portion and is accompanied or followed by a disintegration of the organic substance of the tooth. The cariogenicity of carbohydrate varies with the frequency of ingestion, physical form and chemical composition, route of administration and presence of other food constituents. Sticky solid carbohydrates are more caries producing than those consumed as liquids.

Most commonly associated microorganisms are *L. acidophilus* and *Streptococcus mutans* which are found in caries susceptible individuals. Acids are produced due to enzymatic breakdown of the sugar and the acids formed are chiefly lactic acid and butyric acid.

Autoimmunity

Jackson and Bunch suggest that zones or regions of odontoblasts in specific sites with the pulp of specific teeth are damaged by an autoimmune process so that the defense capacity of the overlying dentin and enamel is compromised and concluded that caries should be regarded as a degenerative process.

Initially disease event corresponds to a form of somatic gene mutation in central growth control stem cells. Descendent mutant cells synthesize autoantibody which damage specific groups of odontoblasts and thus determine the sites of caries susceptibility.

Secondary Factors in Dental Caries

- *Anatomic characteristics of the teeth*
 - *First 2 years after eruption*—teeth are usually susceptible to caries during first 2 years after eruption as additional 2 years are required for completion of calcification after eruption.
 - *First permanent molars*—first permanent molars often have incompletely coalesced pits and fissures that allow the dental plaque material to be retained at the base of the defect in contact with exposed dentin.
 - *Pits on tooth*—lingual pits on the maxillary first permanent molar, buccal pits on the mandibular first permanent molars and lingual pits on maxillary incisors are vulnerable in the process of dental caries proceeds rapidly.
 - *Enamel hypoplasia*—enamel hypoplasia predisposes more to dental caries.
- *Arrangement of the teeth in the arch*—crowded and irregular teeth are not readily cleaned during the natural masticatory process.
- *Presence of dental appliance*—partial dentures, space maintainers and orthodontic appliances often encourage the retention of food debris and plaque material and have been shown to result in an increase in the bacterial population.
- *Saliva factors*—viscosity of saliva has effect on dental caries. Both thick ropy saliva and thin watery saliva have been responsible for rampant caries. Person who has xerostomia is also susceptible for caries.

Classification

First Classification

Based on Location of the Lesion (see Fig. 21-4)

- *Pit and fissure caries*
 - Occlusal
 - Buccal or lingual pit
- *Smooth surface caries*
 - Proximal
 - Buccal or lingual surface
- *Root caries*

Based on Tissue Involved

- Enamel caries
- Dentinal caries
- Cemental caries

Based on Virginity of the Lesion

- Primary caries
- Secondary caries

Based on Progression of Lesion

- Progressive caries
 - Rapidly progressive- like nursing caries and radiation caries
 - Slowly progressive
- Arrested caries

Second Classification

Mount G. J. in 1997 classified dental caries based on site and size.

Site

- *Site 1*—includes lesions on the pit and fissure of the posterior teeth and on other surfaces, these include the buccal grooves of the mandibular molars, palatal grooves of the maxillary molars and erosion on the incisal edges.
- *Site 2*—includes lesions in the contact areas of posterior and anterior teeth.
- *Site 3*—includes lesions originating in the gingival third of all teeth.

Size

- *Size 1 (mild)*—includes lesions which have progressed just beyond remineralization.
- *Size 2 (moderate)*—includes larger lesions with adequate tooth surface to support the restoration.
- *Size 3 (enlarged)*—includes lesions in which the tooth structure and the restoration are susceptible to fracture.
- *Size 4 (severe)*—it includes lesions which have destroyed a major portion of the tooth structure.

Diagnosis of Dental Caries

The search for an ideal caries diagnostic test continues as such test must be accurate, sensitive, specific, reproducible and reliable and should not transfer *S. mutans* or other bacteria from affected area to unaffected areas.

Clinical Method

Visual Inspection

- *Sensitivity of test*—visual inspection is a traditional diagnostic method and it appears to have a very low sensitivity and high specificity in diagnosing caries.
- *Dry and clean teeth*—the teeth should be clean, dry and well illuminated during a visual examination to obtain maximum information.
- *Visual examination*—in detecting occlusal caries has a limited sensitivity. Black or brown discolorations and fissure morphology are not reliable for definitive

diagnosis of occlusal caries. The opacities of the enamel may be more useful in determining caries with visual examination as long as they are not stained but the teeth should be clean, dry and well illuminated.

Explorer

- *Sensitivity of test*—the sensitivity of the explorer is also reported to be low in diagnosing occlusal dentinal lesions. Use of sharp explorers in probing has been questioned by several authors. It is reported that it may cause damage or create a cavity at the site of a superficial carious lesion.
- *How to do it*—using explorer in the intraoral examination may not improve diagnostic accuracy. Sticking probe may not be indicating caries but only be a sign of local anatomical features.
- *Disadvantage*—also probing a sterile fissure after an infected one may inoculate pathogenic microorganisms and infect the sterile fissure. However, in a study which lasted as long as 11 years in which the same children were examined repeatedly as often as six times with vigorous probing of pits and fissures but it didn't show any evidence that probing increases caries. In some parts of the world, especially in Scandinavian countries, applying pressure with sharp explorer is not approved because of the damage, it would create change in the surface integrity and possible implantation of microorganisms. There are some controversial results in this issue but the evidence suggests that an explorer should be used lightly or not at all on occlusal surfaces. In most cases when there is a cavitation on the enamel surface, dentinal involvement is also there.

Radiographic Method

- *Bite wing radiography*—it is used for the diagnosis of proximal decay (**Fig. 21-1**) because caries tends to occur most frequently just below the contact point either mesially or distally.
- *Limitation of radiography in diagnosis of caries*
 - *Two dimensional image*—radiograph must be used with caution as it gives a two dimensional image of three dimensional objects. Due to this the exact site of the carious lesion cannot be located, i.e. buccal or lingual caries, the buccolingual extent of lesion, the distance between carious lesion and the pulp horns and the presence of recurrent caries in existing restoration may completely overlie the carious lesion.
 - *More mineral loss is required for radiographic detection*—another aspect is that the net mineral loss must exceed at least 20% to 30% in order to radiographically visible. Due to this, carious lesions are usually larger clinically than they appear radiographically and very early lesions are not evident at all on radiograph.

Fig. 21-1: Bite wing radiography is useful method for the diagnosis of dental proximal caries.

- *Technical variation*—technical variation in films and X-ray beam position can affect considerably the image of carious lesion, i.e. varying the horizontal tube head angulations can make lesion confined to enamel may appear to have progressed into dentin.

Fiberoptic Transilluminator (FOTI)

- *Sensitivity*—Fiberoptic transilluminator (FOTI) has been used since 1970s in the diagnosis of caries and it is a qualitative method.
- *Method*—a white light emitted from a cold light source is passed through a fiber to an intraoral fiberoptic light probe that is placed on the buccal or lingual side of the tooth. The surface of the tooth is examined using the transmitted light, seen from the occlusal view. Demineralized areas are darker when compared with the sound surrounding tissue. This contrast between sound and carious tissue is then used for detection of lesions.
- *Diagnosis of interproximal caries*—in the diagnosis of interproximal caries, fiberoptic transilluminator (FOTI) can also be used (**Fig. 21-2**). FOTI is reported to be superior to clinical examination and some researchers report that FOTI can detect 70%-90% of dentinal lesions. In terms of diagnostic accuracy and reliability, use of FOTI does not appear to provide any advantage over radiographs for diagnosing interproximal caries in clinical practice. It is difficult to estimate the depth of a lesion or the presence of a cavitation with conventional clinical examination as well as with FOTI in teeth with close interproximal contact.
- *Digital fiberoptic illuminator*—It is relatively new methodology that has developed in an attempt to reduce the shortcomings of FOTI, by combining FOTI and a digital camera. Illumination is delivered on the tooth

surface by means of fiberoptic illuminator which acts as a light source. The resultant change in light distribution is captured by the camera and is sent to the computer for analysis.

21-2: Detection of interproximal caries by using method of fiberoptic transillumination.

Electrical Conductance Measurement

- *Concept*—theory behind this is that sound surface should possess limited or no conductivity, whereas carious or demineralized enamel should have a measurable conductivity that will increase with increasing demineralization.
- *Results*—indicator for caries meter are four colored lights:
 - Green—no caries
 - Yellow—enamel caries
 - Orange—dentin caries
 - Red—pulpal involvement.

Visible Luminescent Spectroscopy

The visible emission spectrum for decayed and non-decayed regions of teeth differs. Quasi monochromatic light from a tungsten source dispersed with a grating monochromatic is focused on the teeth and emission spectra are recorded and analyzed.

Fluorescence

Acid dissolution of the structure results in a local decrease in fluorescence in area of acid exposure (**Fig. 21-3**). This has been used in detection of dental caries.

Use of Caries Detector Dye

Various dyes such as silver nitrate, methyl red and alizarin stain have been used to detect carious sites by change of color. The difficulty lies in removing the dye from the altered enamel area. The altered areas of enamel are characterized

Fig. 21-3: Decreases fluorescence seen in proximal caries area

by more reactive calcium that reacts with carboxylic and sulfonic acid groups of dyes.

Types of Caries (Fig. 21-4)

Interproximal Caries

It is the type of smooth surface caries which is seen in interproximal area between the teeth (Fig. 21-5).

Clinical Features

- *Opaque chalky region*—it takes 3 to 4 years to manifest clinically as loss of enamel transparency resulting in opaque chalky region (white spot). In some cases, it

Fig. 21-4: Different types of carious lesion—a diagrammatic representation.

Fig. 21-5: Proximal caries seen with second premolar and first molar in proximal contact area.

appears as a yellow or brown pigmented area but it is usually well demarcated.

- *Location*—spots are generally located on the outer surface of enamel between contact point and height of free gingival margin. Caries do not initiate below free gingival margin.
- *Progress*—the early white chalky spot becomes slightly roughened owing to superficial decalcification of the enamel. As the caries penetrates the enamel, the enamel surrounding the lesion assumes bluish white appearance (Fig. 21-6) which is usually apparent as laterally spreading caries at the dentinoenamel junction. It is common for proximal caries to extend both buccally and lingually.
- *Pain*—as soon as carious process enter the dentin, patient complaint of sensitivity or pain with carious teeth.

Fig. 21-6: Interproximal carious lesion in anterior teeth showing bluish white appearance.

Radiographic Appearance

- *When it will detect*—radiographic detection of carious lesion on proximal surfaces of teeth depends on loss of enough material to result in detectable changes in radiographic density. As the proximal surfaces of posterior teeth are often broad, the loss of small amounts of mineral is difficult to diagnose on radiograph. 20 to 30% of demineralization is required for detection of lesion.

Fig. 21-7: Triangular shaped radiolucency seen with incisor tooth in proximal caries (Courtesy Dr Fusan Yasser).

- *Appearance*—interproximal carious lesions of enamel are triangular in shape (**Fig. 21-7**) and decrease in volume as they progress towards dentinoenamel junction. As the carious lesion approaches the DEJ, not only it become smaller but it is superimposed with more and more sound enamel which attenuates the X-ray and tends to obscure the demineralized lesion in proportion to its depth.
- *Fracture tooth*—in some cases due to severe caries tooth may get fracture (**Fig. 21-8**).

Radiological Types

- *Incipient caries*—radiographically, this caries susceptible zone has vertical dimension of 1.0 to 1.5 mm. There is loss of normal homogeneity of the enamel shadow (**Figs 21-9A and B**). It appears as a radiolucent notch on the outer surface of teeth. Magnifying glass should be used.
- *Moderate caries*—interproximal incipient lesion that develops and involves more than outer half of enamel but that do not radiographically extends into DEJ may

Fig. 21-8: Fractured tooth due to carious process.

Figs 21-9A and B: Incipient proximal caries showing loss of enamel homogeneity (Courtesy Dr Fusan Yasser).

be called moderate lesion. Once the dentin is involved the margins of the radiolucent areas tapers off gradually into the adjacent tooth substance (**Figs 21-10A and B**). They have three radiographic appearances:

- Most common (67%) is that of triangle with broad base at the surface of tooth.
- Less common (16%) is diffuse radiolucent image.
- Third (17%) is a combination of the two types.

Figs 21-10A and B: Moderate caries seen in incisor region

- *Advanced caries*—these are the lesions that have invaded DEJ. Classically, there is more penetration through enamel. Configuration is usually triangular. It may be diffuse or combination of triangular and diffuse. Spreading of demineralization process at DEJ, undermining the enamel and subsequently extending into dentin which forms second irregular radiolucent image in dentin with base at DEJ and apex directed towards pulp (**Figs 21-11A to D**).

Figs 21-11A to D: Advanced caries showing extension in dentin (Courtesy Fusun Yasser),

Figs 21-12A to C: Severe carious lesion involving more than half of dentin (Courtesy Fusun Yasser).

- **Severe caries**—when carious lesion is seen radiographically to have penetrated through more than half of dentin (Figs 21-12A to C) and is approaching the pulp chamber, it is categorized as severe. It reveals a narrow path of destruction through enamel, the expansion of the radiolucency at DEJ and extends its development toward pulp chamber. It may or may not appear to involve pulp. Force of mastication will cause the undermined enamel to collapse leaving very large cavity or hole in the tooth (Fig. 21-12D).

Fig. 21-12D: Collapse of enamel occurs in severe proximal caries.

Cervical, Buccal, Lingual or Palatal Caries

There are many types of smooth surface caries occurring on cervical, buccal, lingual and palatal.

Clinical Features

- **Location**—it usually extends from the area opposite to the gingival crest occlusally to the convexity of the tooth surface. It extends laterally towards the proximal surfaces and on occasion extends beneath the free margin of the gingiva.
- **Cervical lesion**—it usually occurs in cervical area and the typical cervical lesion is a crescent shaped cavity (Fig. 21-13). Beginning as slightly roughened chalky area which gradually becomes excavated.
- **Buccal pit**—this again one of common type of caries which occur as pit on the buccal surface of tooth (Fig. 21.14).

Fig. 21-13: Crescent shaped carious lesion of cervical caries.

Fig. 21-14: Buccal pit present on the buccal surface of tooth.

Radiographic Features

- It is difficult to differentiate between buccal and lingual caries on a radiograph.
- Appearance—there is uniform radiopaque circular region (Fig. 21-15) representing parallel non-carious enamel rod surrounding the buccal or palatal decay.

Pit and Fissure Caries

It is also called as 'occlusal caries'. It is primary type and develops in the occlusal surface of molars and premolars (Fig. 21-16). Deep narrow pits and fissures favor the retention of food debris and microorganisms and caries may result due to fermentation of food and the formation of acids.

Fig. 21-15: Labial caries showing circular radiolucency.

Fig. 21-16: Deep pits and fissure more prone for carious tooth.

Clinical Features

- **Location**—it usually occurs in pits and fissures with high steep walls and narrow bases.
- **Appearance**—it appears brown or black (Figs 21-17A and B) and feels slightly soft and catches a fine explorer point. The enamel directly bordering the pit and fissure may appear opaque, bluish white as it becomes undermined.
- **Spread**—the lateral spread of caries at the dentinoenamel junction as well as penetration into the dentin along the dentinal tubules may be extensive without fracturing away the overhanging enamel. Thus, there may be large carious lesion with only a tiny point of opening.

Radiological Features

- **Common errors**—three common errors made in interpretation of occlusal caries are.
 - Failure to recognize that occlusal caries of enamel will not ordinarily be detected in the radiograph because of superimposition of heavy cuspal enamel over fissure area.
 - Carelessness in not observing rather long thin radiolucency that first appears at DEJ.
 - Confusion in distinguishing between occlusal and buccal caries.
- **Incipient lesion**—radiograph is not effective for the detection of an occlusal caries unless it reaches the dentin. The only change at the occlusal surface produced by early lesion is fine gray shadow just under the DEJ. Carious lesion generally starts at the side of fissure wall rather than its base. The lesion tends to penetrate nearly perpendicular to DEJ.
- **Moderate lesion**—there is broad base with thin radiolucent zone in the dentin with little or no changes in enamel (Fig. 21-18). There is band of increased opacity between carious lesion and pulp chamber.

Figs 21-17A and B: Pit and fissure carious lesion brown black discoloration of tooth.

Fig. 21-18: Moderate occlusal carious lesion seen on 2nd molar.

- *Severe lesion*—large hole or cavity in the crown of the teeth (**Figs 21-19A to C**) Masticatory stress causes collapse of enamel.

Root Caries

It is also called as '*cemental caries*' and involves both dentin and cementum. Nowadays, there is greater prevalence of

Figs 21-19A to C: Severe occlusal carious lesion showing large hole in tooth.

root caries due to longer lifespan of persons, with the retention of teeth into the later decades of life and increase in the number of people exhibiting gingival recession with clinical exposure of cemental surface. Freshly exposed root are more vulnerable to an acid attack because of higher porosity and smaller crystal.

Clinical Features

- *Site*—it appears as slowly progressing chronic lesion. It is usually found in mandibular molar and premolar region. Tooth surface involved in decreasing order of frequency are buccal, lingual and interproximal.
- *Associated features*—gingival recession is associated with root surface caries (**Fig. 21-20**).

Fig. 21-20: Root surface caries seen in incisor region.

Radiographic Features

- *Appearance*—the carious process is best described as scooping out which result in radiographic appearance usually described as ill-defined saucer-like crater. If peripheral surface area is small, the appearance of carious lesion will be notched rather than saucer-like.

Recurrent Caries

Dental caries that occurs immediately adjacent to the restoration is referred to as recurrent caries (**Fig. 21-21**). It may be caused by inadequate extension of restoration and there has not been careful and complete excavation of original carious lesion.

Clinical Features

- *Incidence*—16% of restored teeth have recurrent caries.
- *Cause*—restoration will show poor margins which permit leakage and the entrance of both bacteria and substrate.

Fig. 21-21: Recurrent carious lesion seen below the restoration of tooth.

Radiographic Features

- *Appearance*—teeth have areas of increased radiolucency along the margins of the restoration. Recurrent caries that occurs at mesioingival, distoingival and occlusal margins are more frequently discovered than that which occurs at margins of buccal, facial and lingual restorations (**Figs 21-22A to E**).
- *Difficulty in diagnosis*—in dental amalgam mercury is mixed with an alloy powder containing silver, tin and zinc. With passage of time, tin and zinc ions are released into the underlying demineralized dentin producing a radiopaque zone within the dentin which follows the S-shaped curve of the underlying tubules. The radiopacities of this zone make the normal dentin on either side appear more radiolucent by contrast simulating recurrent caries and leading to difficulty in diagnosis.

Nursing Bottle Caries

This occurs in child who use nursing bottle in bed which contain milk or milk formulae, fruit juice or sweetened water. This type of caries is also prevalent in sugar or honey-sweetened pacifier.

Pathogenesis

The reasons for this are that the child is put on bed at afternoon nap time or at night with nursing bottle containing milk or a sugar containing beverage. The child fall asleep and the milk or sweetened liquid becomes pooled around the maxillary anterior teeth. The carbohydrate containing liquid provides an excellent culture medium for acidogenic microorganisms. Salivary flow is decreased during sleep and clearance of the liquid from the oral cavity is slowed. Lactose content of human milk, as well as that of

Figs 21-22A to E: Recurrent caries seen below the restoration (Courtesy Fusan Yasser).

bovine milk, can be cariogenic if the milk is allowed to stagnate on the teeth.

Clinical Features

- *Site*—there is early carious involvement of the maxillary anterior teeth (**Figs 21-23A and B**), the maxillary and mandibular first permanent molars, the mandibular canines.
- *Appearance*—the carious process in the teeth is so severe that only the root stumps remain.

Prevention

- *Holding the infant*—the infant should be held while feeding.
- *Remove the bottle from child mouth while he falls asleep*—the child who falls asleep while nursing should be burped and then placed in bed.

Figs 21-23A and B: Nursing bottle caries seen in maxillary anterior teeth (Courtesy Dr Shetty).

- *Brushing of child teeth*—parent should start brushing the child teeth as soon as they erupt in the oral cavity.
- *Discontinue bottle feeding after the age of 12 to 15 months*—discontinue bottle feeding as soon as child can drink from a cup, at approximately 12 to 15 months of age.

Radiation Caries

It is a rampant form of dental decay that may occur in individuals who receive a course of radiotherapy that includes exposure of the salivary glands.

Clinical Features

- *Appearance*—destruction begins at cervical region. The lesion may aggressively encircle the tooth causing the entire crown to be lost with only root fragment remaining in the jaws.
- *Clinical types*—clinically there are three types of radiation caries:
 - *Widespread superficial lesion*—it attacks buccal, occlusal, incisal and palatal surfaces.
 - *Circumferential caries*—it usually occurs in cementum and dentin in the cervical region. It may result in loss of the crown.
 - *Pigmentation of crown*—it is usually dark in color.

Radiological Features

- *Appearance*—radiographically it appears as dark radiolucent shadow appearing at necks of teeth most obvious on mesial and distal aspects.

Rampant Caries

It is defined as a suddenly appearing, widespread, rapidly burrowing type of caries, resulting in early involvement of the pulp and affecting those teeth usually regarded as immune to ordinary decay. Some believe that the term rampant caries should be applied to those carious lesions with 10 or more new lesions per year. It usually occurs in children with poor dietary habits.

Etiology

- *Systemic disease*—nutritional deficiency, malnutrition may lead to rampant caries.
- *Emotional disturbance*—emotional disturbances may be causative factors in some cases of rampant caries.
- *Stress and medication*—various forms of stress in both children and adults, as well as various medication (such as tranquilizers and sedatives) commonly taken to help persons cope with stress, are associated with decreased salivary flow and decreased caries resistance caused by impaired remineralization.

Clinical Features

- *Appearance*—it demonstrates extensive interproximal and smooth surface caries (**Figs 21-24 and 21-25**).
- *Occurrence*—rampant caries can occur suddenly in teeth that were for many years relatively immune to decay.

Fig. 21-24: Rampant form of caries showing total destruction of tooth surface in mandibular teeth.

Fig. 21-25: Rampant form of caries seen in mandibular teeth.

Radiographic Features

- *Appearance*—it demonstrate severe advanced carious lesions especially of mandibular anterior teeth.

Arrested Caries

It has been described as caries which becomes static or stationary and does not show any tendency for further progression.

Clinical Features

- *Location*—both deciduous and permanent dentitions are affected by this condition. It occurs exclusively in caries of occlusal surfaces.
- *Appearance*—it is characterized by large open cavities in which there is lack of food retention and in which the superficially softened and decalcified dentin is gradually burnished and has taken a brown-stained polished appearance and is hard. This has been referred to as 'eburnation of dentin'. In some cases, there is brown stained area at or just below the contact of the affected tooth.

Radiological Features

- *Appearance*—radiographically, these arrested carious lesions appear as small radiolucent areas (**Fig. 21-26**). Sometimes large occlusal carious lesions also arrest. In these lesions, there is an open cavity which is easily observed clinically.
- *Crown of tooth*—the crown of the tooth is absent and there is a radiolucent area in this region. Due to the defensive measure of the pulp to limit the carious lesion, there might be a sclerotic line under the radiolucent area.

Fig. 21-26: Arrested caries showing small radiolucent area (Courtesy Dr Fusun Yasser).

Pre-eruptive Caries

Occasionally, defect on the crowns of developing permanent teeth are evident radiographically, even though no infection of the primary tooth or surrounding area is apparent. Such lesions resemble caries when it is observed clinically and the destructive nature of lesion progresses if it is not restored.

As soon as the lesion is reasonably accessible, the tooth should be uncovered by removal of the overlying primary tooth or by surgical exposure.

Linear Enamel Caries

This type of caries is seen in deciduous dentition in anterior maxillary teeth. Linear enamel caries is caused by metabolic disturbances or trauma. It is present in the region of neonatal line.

Acute Dental Caries

This type of caries runs rapid course and characterized by pulpal involvement in early course of caries. It is most commonly seen in young adults. The typical feature of acute dental caries is that, there is small opening, which will result in less contact of saliva with the carious process. This will result in less buffering and neutralization of acid. So the process will rapid. Pain is the constant feature of this disease.

Chronic Dental Caries

This is slow process and involvement of pulp occurs in a late stage. The opening of this carious process is large, resulting in less food retention. The dentin stained brown in this type of caries. There is little undermined enamel. Pain is not common feature of this disease.

Radiographic Differential Diagnosis of Dental Caries

- *Erosion cavity*—since these cavities are saucer shaped and have sloping margins in radiographs, they may resemble carious cavities. Clinical examination is necessary to rule out erosion cavity.
- *Non-opaque filling*—if carious cavities are filled with non-opaque filling material then it may resemble caries. But sharpness of the margin surgically prepared suggests the presence of filling.
- *Cervical burnout*—following is the difference between cervical burnout and cervical caries—
 - Cervical burnout is located at the neck of the teeth, demarcated above by the enamel cap or restoration and below by the alveolar bone level while caries have no apparent upper and lower demarcating borders.
 - It is triangular in shape, gradually becoming less apparent towards the center of the tooth while caries is saucer shaped and becomes more apparent toward center of tooth.
 - In cervical burnout axial border fades or follows anatomic contour while in case of cervical caries sharp delineation and ragged contour is present.
 - Peripheral outline of cervical burnout appear intact as compared to caries where it is cavitated.

- Usually all the teeth on the radiograph are affected, especially the smaller premolars while the caries is localized.
- *Internal resorption*—some of the cases will show pink tinge where the vascular pulp lies beneath the thin dental tissue. Margins of internal resorption are sharply defined as compared to caries which has fading margin due to decalcification. If the pulp chamber has its normal margin effaced, it is suggestive of internal resorption rather than caries.
- *External resorption*—only if the destruction is at the cervical portion of the tooth. External resorption may be mistaken for dental caries. In resorption, the line of demarcation between adjacent tooth substance and the defective area is sharp without any decalcification beyond the precise site of tooth destruction
- *Hypoplasia of enamel*—in hypoplasia, the radiolucent area is not single and it is common that several small dark spots cross the tooth. Visual inspection rule out the hypoplasia.

Control of Dental Caries

Control of all Active Lesions

Initial treatment of all active lesions should be done. Gross excavation of all carious lesions followed by restoring a tooth to normal contour is done.

Nutritional Measures for Caries Control

Group of patients whose diet is high in fat, low in carbohydrate and practically free from sugar have low caries activity. In a study, when refined sugar was added to the diet in the form of a mealtime supplement, there was little or no caries activity. Phosphates diet causes significant reduction in incidence of caries.

Mechanical Measures for Caries Control

- *Toothbrushing*—tooth brushing reduces the number of oral microorganisms, particularly if the teeth are brushed after each meal. Tooth brush also removes gross amounts of food debris and plaque material.
- *Mouth rinsing*—the use of mouthwash for the benefit of its action in loosening food debris from the teeth has been suggested as a measure of caries control.
- *Dental floss*—dental flossing has been shown to remove plaque from an area gingival to the contact areas on proximal surfaces of teeth, an area impossible to reach with toothbrush.

- *Detergent*—some workers have related the high caries incidence among modern civilized races to the unrestrained use of soft, sticky, refined foods, which tend to adhere to the teeth. It has been stated that fibrous food prevents lodging of food in pits and fissures of teeth and in addition acts as detergent.
- *Oral irrigators*—this is more useful in management of gingival infection.
- *Chewing gums*—this can prevent dental caries mechanical cleansing action.
- *Pit and fissure sealants*—pits and fissures of occlusal surface are among the most difficult areas on teeth to keep clean and from which to remove plaque. The pit and fissure sealants generally used in conjunction with an acid pretreatment to enhance their retention, contain either cyanoacrylate, polyurethane or the adduct of bisphenol A and glycidyl methacrylate.

Chemical Measures of Caries Control

- *Fluorine*—the cariostatic activity of fluoride involves several different mechanisms. The ingestion of fluoride results in its incorporation into the dentin and enamel of unerupted teeth. This makes the teeth more resistant to acid attack after eruption into oral cavity. In addition, ingested fluoride is secreted into saliva; although present in low concentration in saliva; the fluoride is accumulated in plaque where it decreases microbial acid production and enhances the remineralization of the underlying enamel. Fluoride from saliva is also incorporated into the enamel of newly erupted teeth, thereby enhancing the enamel calcification.
 - *Communal water fluoridation*—fluoridation of the communal water supply is the most effective method of reducing the dental caries problems in the general population.
 - *Fluoride containing dentifrices*—it contains stannous fluoride in combination with calcium pyrophosphate as the cleaning and polishing system and was accepted as the first therapeutic dentifrice.
 - *Fluoride mouth rinses*—it should be given cautiously in children under 4 years of age as they may not have full control over the swallowing reflex.
 - *Dietary fluoride supplement*—the administration of fluoride supplement commences shortly after birth and should continue through the time of eruption of the second permanent molars.
- *Bisbiguanides*—chlorhexidine and alexidine are potential anticaries agents as they are antiplaque agents. It has been shown that chlorhexidine is adsorbed onto tooth surface and salivary mucins then it is released slowly in an active form. But disadvantage of chlorhexidine is that it has bitter taste, produces brownish discoloration of hard and soft tissues and may produce painful desquamation of mucosa.
- *Silver nitrate*—silver nitrate impregnation of teeth was used for many years to prevent or arrest caries. Silver plugs the enamel by either the organic invasion pathways such as the enamel lamellae or the inorganic portion of enamel to form a less soluble combination.
- *Zinc chloride and potassium ferrocyanide*—use of solution of zinc chloride and potassium ferrocyanide would effectively impregnate the enamel and seal off caries invasion pathways. But study shows that it is of little value in reduction of caries.
- *Vitamin K*—synthetic vitamin K (2-methyl 1, 4 naphthoquinone) prevents acid formation in incubated mixture of glucose and saliva. In study also it has shown to decrease incidence of caries formation in persons given chewing gums containing vitamin K.
- *Sarcoside*—persons who brushed teeth with dentifrices containing sodium N-lauroyl sarcosinate have been shown to have decreased incidence of caries. It has been stated that it has got ability to penetrate the dental plaque and prevent pH to fall below 5.5 after carbohydrate rinse.
- *Urea and ammonium compounds*—reports suggest that a quinine urea mouthwash prevents acid formation in test *in vitro* on carbohydrate saliva mixtures. It may also be noted that oral bacteria count was decreased after the use of quinine urea mouthwash and salivary pH generally increased to value over 8 and remained high for approximately an hour. The evidence indicated that urea upon degradation by urease; release ammonia which act to neutralize the acids formed through carbohydrate digestion and also interferes with bacterial growth. Although there are some studies to indicate that ammoniated dentifrices are capable of producing some reduction in dental caries incidence, the magnitude of this reduction, particularly in persons whose tooth-brushing habits are not controlled or supervised, is not so great as to justify recommending them for widespread use as an anti-cariogenic agent.
- *Chlorophyll*—it is a green pigment of plants and has been proposed as an anti-cariogenic agent on the basis of a number of *in vitro* studies and animal studies. Water soluble form of chlorophyll, sodium copper chlorophyllin, was capable of preventing or reducing the pH fall in carbohydrate-saliva mixtures *in vitro*.
- *Nitrofurans*—they are derivatives of furfural which itself is derived from pentoses. They have been found to exert bacteriostatic and bactericidal action on many gram-positive and gram-negative bacteria and they can also inhibit acid formation. Studies show that nitrofurans compounds like furadroxyl (5-nitro-2-furaldehyde-2-hydroxyethyl semicarbazone) reduce dental caries.

- *Penicillin*—it has got ability to inhibit the normal biologic processes of lactobacilli which is one of the etiological factors in the dental caries. Penicillin is given in dentifrices.

Introduction

The tongue makes up a large part of the oral cavity and can be affected by numerous lesions. The tongue may be affected as a part of oral disease or as a signs of a systemic disease. The word 'tongue' is derived from the Latin word '*lingua*' and Greek word '*glossa*'. It is partly oral (anterior 2/3rd of tongue) and partly pharyngeal (posterior 1/3rd of tongue). It is composed of body (movable oral part) and base (attached part).

Embryology and Development of Tongue

- *Origin*—the tongue develops from the ventral wall of the primitive oropharynx. It is derived principally from first, second and third branchial arch as well as from occipital myotomes.
- *Tuberculum impar*—tuberculum impar is the three centrally placed elevations on the ventromedial portion. But soon, elevations of the ventromedial portion of the 1st arch arise on each side of tubercle and merge with each other.
- *Foramen cecum*—there is transient elevation present on caudal border of tuberculum impar which is marked by a blind pit. This is called as foramen cecum.
- *Lingual swelling*—during the 4th week of development, paired lateral thickening of mesenchyme appears on the internal aspect of 1st branchial arch. This is called as lateral lingual swelling. Lateral lingual swelling merge with each other and overgrow the tuberculum impar to form the oral part of tongue.
- *Formation of anterior two-third of tongue*—anterior 2/3rd is formed by fusion of tuberculum impar and two lateral lingual swelling.

- *Formation of posterior 1/3rd of tongue*—the posterior 1/3rd of the tongue has a more complicated developmental origin. It first exists as a central mound called *the copula*, which is the result of fusion of the 3rd branchial arches. The endodermally derived mucosa of the 2nd to 4th branchial arches and the copula, provide covering for the posterior thirds of the tongue.
- *Sulcus terminalis*—it is the site of union between the base and the body of tongue. It is V shaped groove.
- *Occipital myotomes*—it migrates anteriorly into the tongue during fifth to seventh week. In a later stage various types of papillae differentiated in the dorsal mucosa of the body of tongue.
- *Tongue innervations*—ninth and twelfth nerves are carried along the migrating tongue mass. This mass then picks seventh and fifth nerve as it approaches the oral cavity.

Anatomy of Tongue

The tongue is a muscular organ situated in the floor of mouth, associated with the function of deglutition, taste and speech. Tongue has a base, body and a tip. It has two surfaces, a dorsal and a ventral surface. The dorsal surface is divided into an oral and pharyngeal part and the ventral surface is confined to the oral cavity only.

Surface

- *Sulcus terminalis*—it lies partly in the mouth (oral part), which comprises the anterior 2/3rd and in the pharynx (pharyngeal part), which comprises the posterior 1/3rd. Both the parts are separated by the inverted 'V' shaped sulcus called the *sulcus terminalis*. At the apex of sulcus terminalis, there is a depression, called *the foramen cecum*.
- *Anterior part*—in the anterior part of the tongue the mucous membrane is thin with reduced lamina propria

and is closely attached to the underlying muscular tissue. The color of the anterior part of the mucous membrane is pink and is marked by a variety of papillae that gives the tongue a characteristic roughness. The anterior part of the tongue is divided in half by the *median lingual sulcus*.

- *Posterior part*—the posterior part also called as *pharyngeal part* or base of the *tongue* is located posterior to the palatoglossal arch.
- *Lingual tonsil*—the surface without papillae shows a slightly corrugated appearance, due to the underlying lymphoid tissue called the *lingual tonsil*.
- *Root of tongue*—the root of the tongue is attached to the epiglottis by a medial fold (the glossoepiglottic fold). Laterally, pharyngoepiglottic (glossopharyngeal) folds pass from the sides of the tongue and pharyngeal wall to the epiglottis. The root of tongue is attached to the hyoid bone, below and the mandible above.
- *Ventral surface*—the ventral surface is smooth and purplish with no papillae. On the ventral surface, lingual veins are often visible as bluish streaks.
- *Lingual frenulum*—the tongue is connected to the floor of the mouth by a sickle shaped fold of mucous membrane called as *lingual frenulum*. Anteriorly, on either side of the frenulum, the *caruncles* opening for the submandibular ducts are visible.
- *Plica fimbriata*—at the lateral side of the vein, a fringed fold of mucous membrane called as the *plica fimbriata* or *fimbriated fold*.
- *Taste buds*—these are peripheral gustatory organs which are composed of modified epithelial cells. They are most numerous on the sides of circumvallate papillae and less on the walls surrounding the foliate papillae. They are more numerous in infants than in adults. With age, they undergo atrophy.

Papillae

- *Circumvallate papillae*—they are usually 8 to 12 in number and are the largest of the papillae. They are situated in a row parallel to and close to the sulcus terminalis. Papillae are 1 to 3 mm in diameter and are flattened with a circular depression. They are surrounded by a moat-like trough.
- *Fungiform papillae*—they are smaller than the vallate papillae and are distributed over the dorsal surface of the tongue, being most numerous on the anterior part. They are round and mushroom shaped and is distinguished from the filiform papillae by their larger size and bright red color. Their number is about 100/cm² on the tip and 50/cm² in the middle. They carry taste buds.
- *Filiform papillae*—these are smallest, but most numerous and are evenly distributed over the dorsum and are often

arranged in rows parallel to the sulcus terminalis, except for the tip where they run transversely. The papillae are conical, broadest at the base and whitish due to marked degree of keratinization. The concentration of papillae in man is calculated about 500/cm². They are more heavily concentrated in center of dorsum of tongue.

- *Foliate papillae*—they are vertical folds of the mucosa located at the margins of the tongue, just anteriorly to the palatoglossal arch.
- *Papillae simplices*—they are connective tissue papillae which are similar to the papillae of dermis of skin. They are present beneath the entire tongue surface, including the mucosal papillae described above.

Muscle

- *Types of muscle*—the muscles of tongue are grouped into two sets: an extrinsic set and an intrinsic set. The extrinsic muscles include genioglossus, hyoglossus, styloglossus and palatoglossus.
- *Genioglossus*—it is the largest and arises from the upper mental spine and spread in a fan-like fashion and is inserted into the tongue from its tip to the root. It draws the tongue forward and acting together. This muscle is able to flatten the tongue, making a concavity from side-to-side.
- *Hyoglossus*—it is a flat, quadrilateral muscle arising from the hyoid bone. It runs as thin plate upward, connect with fibers from the styloglossus and enter the tongue lateral to the genioglossus. It depresses the tongue.
- *Styloglossus*—it originates from the styloid process, passes downwards and forwards and inserts into the side of the tongue, connecting with fibers from the hyoglossus. The styloglossus draws the tongue upwards and backwards.
- *Palatoglossus*—it originates from the palate and runs in the palatoglossus arch, continuing into the side and dorsum of the tongue.
- *Intrinsic muscles*—these are situated inside the tongue and constitute a greater part of the organ. They are divided into the superior longitudinal, inferior longitudinal, transverse and the vertical muscles.
 - *Superior longitudinal*—it arise from submucous fibrous layer close to the epiglottis and from the median fibrous septum. It runs forward to the edges of tongue, some of its fibers being inserted into mucous membrane. It shortens the tongue and makes the dorsum concave, by turning the tip and side of the tongue upward.
 - *Inferior longitudinal*—it is a narrow band lying close to the inferior surface of tongue, between genioglossus and hyoglossus. It extends from the root apex of the tongue, some of its posterior fibers being connected with the body of hyoid bone. In front, it blends with the fibers of styloglossus. It shortens the tongue and

makes its dorsum convex by pulling the tip of tongue downwards.

- *Transverse muscle*—it originates from the median fibrous septum and runs in horizontal course, laterally to be inserted into submucous fibrous tissue. By their action, intrinsic muscles alter the shape of the tongue making it narrow and elongated.
- *Vertical muscle*—it is found at the borders of anterior part of tongue. Its fibers extend from dorsal to ventral surface, mainly near its lateral borders, but fibers are interspersed through the tongue. It makes the tongue broad and flattened.

Arterial Supply

- *Lingual artery*—the lingual artery, a branch of the external carotid, is the main vessel supplying the tongue. Before the artery reaches the posterior edge of the hyoglossus muscle, it gives off a branch to the hyoid bone area.
- *Lingual dorsal artery*—in its course below the hyoglossal muscle, it gives off a lingual dorsal artery, which runs steeply upward dividing into many branches supplying the base of tongue and posterior part of the dorsum.
- *Ascending pharyngeal artery and tonsillar artery*—the root of the tongue is also supplied by the ascending pharyngeal artery and tonsillar artery.
- *Sublingual artery*—at the lower border of the anterior part of the hyoglossal muscle, the lingual artery gives off the sublingual artery, which supplies the sublingual region medial to the sublingual gland.

Venous Drainage

- *Lingual vein*—deep lingual vein is the largest and the principal vein of the tongue. Deep lingual vein originates near the tip of the tongue and runs backward, close to the mucous membrane on the ventral surface of the tongue.
- *Vena comitans*—it joins the sublingual vein, at the posterior border of the hypoglossal muscle to form the *vena comitans* of the hypoglossal nerve, which drains to the facial or internal jugular vein.
- *Dorsal lingual vein*—the dorsal lingual vein drains into the dorsum and sides of the tongue. It joins the sublingual veins, which follow the artery deep to the hypoglossal muscle and enter the internal jugular vein, near the hyoid bone.

Nerve Supply

- *Hypoglossal nerve*—all the muscles of the tongue, except the palatoglossus are supplied by the *hypoglossal nerve*. The palatoglossus is supplied by the pharyngeal plexus.
- *Lingual branch* of mandibular nerve is nerve for general sensation for anterior 2/3rd of tongue.

- *Glossopharyngeal nerve* is the nerve for general sensation for posterior 1/3rd of the tongue.
- Posterior most part of tongue is supplied by vagus nerve, through *internal laryngeal nerve*.
- Taste sensation is carried out by *chorda tympani* branch of facial nerve for anterior 2/3rd and glossopharyngeal nerve for posterior 1/3rd.

Lymphatic Drainage

- *Submental nodes*—the tip of the tongue drains bilaterally into the submental nodes.
- *Submandibular lymph nodes*—right and left halves of rest of the anterior 2/3rd of the tongue, drain unilaterally to submandibular lymph nodes. A few central lymphs drain laterally into the same nodes.
- *Jugulodigastric nodes*—some of the lymph vessels, from the lateral margins of the tongue, drain to the jugulodigastric nodes.
- *Jugulo-omohyoid nodes*—the posterior 1/3rd of the tongue drain bilaterally to the jugulo-omohyoid nodes, in which most of the lymphs drain from the tongue.

Functions of Tongue

- *Speech*—it is the result of interaction between different organs. Even small changes in the position or shape of the tongue may cause disturbance in speech. Tongue is one of the organs in the oral cavity, which interrupts the air passage through mouth or pharynx thereby producing consonants. Certain consonants like c, d, j, i, n, t, z, l, g, etc. require movement of tongue.
- *Mastication*—the tongue has a direct crushing effect on food by pressing it against the hard palate. The tongue pushes the food onto the occluding surfaces and helps to mix in the saliva. The sensory ending on the tongue enable to select those parts of the food mass are sufficiently well masticated to be ready for swallowing.
- *Deglutition*—when the food bolus is placed on dorsum of tongue, it is pressed lightly against the hard palate just behind the incisors. It is a coordinated muscular activity involving the tongue and constrictor muscle of the pharynx, to close the palatal vault and the epiglottis. It allows the passage of the bolus into the esophagus, without regurgitation into the nose or lower respiratory tract. The process is initiated by the voluntary action of collecting food onto the tongue and propelling it backwards into the pharynx. The muscles involved in this process are the mylohyoid and the pharyngeal constrictors. Bolus is pushed backwards by raising the back of tongue. Food bolus is sucked from mouth into pharynx, by creating a negative pressure, while airways

are still closed by rapid relaxation of muscles of tongue and pharynx.

- *Digestion*—tongue has a slight digestive function by virtue of salivary lipase, present in serous lingual salivary glands.
- *Taste*—it acts as a special sense organ of taste, by virtue of presence of numerous taste buds. The tip of the tongue is most sensitive to substances eliciting a sweet sensation. The lateral margins are most sensitive to substances causing sour sensation. The base of the tongue is most sensitive to substances eliciting a bitter sensation. The salty quality is more widespread, but is greatest at the tip.
- *Barrier function*—mucosa covering the tongue acts as a barrier protecting the deeper tissues from mechanical damage. It also prevents entry of microorganisms and toxic substances.
- *Jaw development*—muscular pressure from the tongue is an important factor in determining the shape of the mandibular arch.
- *Thermal regulation*—it is more pronounced in dogs, where there is a considerable loss of heat from the tongue.
- *Secretion*—major secretion of tongue is provided by salivary glands activity which maintains the moist surface of oral mucosa.
- *Defense mechanism*—secretory immunoglobulin system of tongue plays an important role in body defense.
- *Maintenance of oral hygiene*—by virtue of its movement it can reach all parts of the oral cavity removing food debris from the gums, vestibule and floor of mouth. Thus, it helps in maintenance of oral hygiene.
- *Sucking*—tongue also plays an important role in sucking in both bottle feeding and breastfeeding.
- *General sensitivity*—due to extreme sensory innervations terminating in both simple and organized nerve endings, there is perception of heat, cold, pressure and chemical discrimination.
- *Symbolic function*—functions that are traditionally associated with the tongue, but that have no anatomic and physiologic basis should be mentioned because images of this type are well established, cultural and literary tradition. It must frequently influences a patient perception of a lingual abnormality. Expressions such as 'speaking with a forked tongue' or 'speaking in different tongue' all describe the mental attitude and behaviors, by which they are expressed.

Specialized Examination of the Tongue

- *Cineradiography*—cineradiographic studies of the oral cavity and pharynx during drinking, chewing, suckling,

phonation and other activity, have added immeasurable to our understanding of the position and shape of the tongue in motion. It also helps in the diagnosis of abnormalities of swallowing, phonation and other functions, associated with congenital and surgically induced defects.

- *Computer assisted tomography*—it is used for number of instances to identify the space occupying lesion and muscular atrophy secondary to hypoglossal nerve damage, where the lesion was deep in the base of the tongue.
- *Pulsed (Doppler) ultrasound*—it is used to study the characteristic of arterial blood flow in the tongue and abnormal pulse wave in the lingual artery of individuals with evidence of compromise flow in other branches of carotid artery.
- *Real time ultrasound*—in it, probes of sufficiently small cross sectional diameter are used for exploring the ventral surface of the tongue. It is used to produce image of a cyst or other lesion within the tongue and also to estimate tongue size.
- *Isotopic scanning technique*—it is useful where the mass in the tongue is composed of specialized secretory tissue or other tissue, such as thyroid, which selectively concentrates intravenously administered radioactive elements.
- *Electromyography*—it is used to study the action potential in actively contracting muscles. It has contributed to an understanding of lingual and masticatory muscular function.
- *Scanning electron microscope*—it is useful for studying the surface topography of the tongue dorsum and the character and morphology of different types of tongue papillae.
- *Transmission electron microscopy*—it is used to study the pathologic changes in the taste buds in xerostomia and lesions of the 7th and 9th cranial nerves.
- *Taste testing*—the midline of the tongue and the V-shaped row of papillae separates the tongue into four quadrants. The anterior two of which bear fungiform papillae, with gustatory receptors connected via the right and left lingual branches of the 5th cranial nerve to the chorda tympani and facial nerve. The posterior two quadrants include the right and left vallates and the pharyngeal surface of the tongue, innervated by gustatory fibers of the lingual branches of the right and left glosso-pharyngeal and possibly, the vagus nerve. Testing of these four quadrants, thus, allows separation of abnormalities of the right and left side and 5th versus 9th cranial nerve function. Tongue must be dried or rinsed between each application of testant and it must be held in extruded position from the time of each

Table 22-1: Classification of tongue disorders

Developmental		
• Aglossia or hypoglossia	• Adenoma	• Syphilitic mucus patches
• Ankyloglossia	• Hemangioma	• Verruca vulgaris
• Bifid tongue	• Lymphangioma	
• Lingual polyp		Neurologic
• Macroglossia	Malignant	• Dyskinesia—involuntary movements
• Midline fistula	• Squamous cell carcinoma	• Glossodynia
• Teratoma	• Adenocarcinoma	• Trigeminal neuralgia
• Median rhomboid glossitis	• Transitional cell carcinoma	• Glossopharyngeal neuralgia
	• Verrucous carcinoma	• Polyneuritis
	• Mucoepidermoid carcinoma	• Neurofibromatosis
	• Reticular cell carcinoma	• Tongue thrusting
Infectious		• Dysgeusia
• Bacterial	Metastatic lesions from	
• Fungal and saprophytic	• Kidney	Papillary changes in tongue
• Parasitic	• Liver	Atrophic
• Viral	• Stomach	• Median rhomboid glossitis
	• Lung	• Geographic tongue
Cystic		• Pernicious anemia
• Epidermoid	Fissured tongue	• Protein deficiency
• Dermoid	• Congenital	• Lichen planus
• Lymphoepithelial	• Syphilis	• OSMF
• Mucus	• Amyloidosis	• Scleroderma
• Anterior median lingual cyst	• Melkersson-Rosenthal syndrome	
• Gastric mucosal cyst	• Papillon-Lefevre syndrome	Hypertrophic
• Parasitic cyst	• Traumatic bite	• White and black hairy tongue
• Bronchogenic cyst	• Lymphosarcoma	• After antibiotic therapy
	• Angiosarcoma	• After steroid therapy
	• Kaposi's sarcoma	• Hydrogen peroxide mouth wash
Neoplastic	• Melanoma	• Immunosuppressive drugs
Benign	Red and white lesions	• Smoking
• Fibroma	• Leukoplakia	• High fever
• Granular cell myoblastoma	• Erythroplakia	• Constipation
• Glomus tumor	• Lichen planus	• Hyperacidity
• Leiomyoma	• OSMF	
• Rhabdomyoma	• Candidiasis	Systemic diseases manifested in tongue
• Rhabdomyosarcoma	• Psoriasis	• Infections—bacterial, viral and fungal
• Neurofibroma	• Focal epithelial hyperplasia	• Blood disorders

• Traumatic neuroma	• Pemphigus	• Dermatological disorders
• Papilloma		• Collagen and autoimmune disorders

application until the patient gives his response. The drops of solution are best applied with the help of a pipette, rather than a cotton swab. The patient should be allowed to rinse his mouth with tap water, from time to time and to retract his tongue and relax between tastes.

Classification of Tongue Disorders

Classification of tongue disorders is discussed in Tables 22-1 to 22-3.

Congenital and Developmental Disorders

Aglossia and Microglossia

Definition

- *Aglossia*—it is the complete absent of tongue at birth.
- *Microglossia*—it is the presence of small rudimentary tongue.

Clinical Features

- *Symptoms*—patient encounters difficulty in eating and speaking.
- *Signs*—patient may have high arched palate and a narrow constricted mandible.
- *Airway problems*—there may be an airway obstruction, due to negative pressure generated by deglutition and inspiration.
- *Syndrome associated*—oromandibular limb hypogenesis syndrome (hypodactylia) and hypomelia and Pierre Robin syndrome.

Diagnosis

It can diagnose on clinical examination.

Management

- Non-surgical technique such as positioning, nasogastric intubation and temporary endotracheal intubation can be carried out to prevent airway obstruction.

Table 22-2: Classification of tongue disorders

Inherited, congenital and developmental anomalies**Minor variations**

- Partial ankyloglossia
- Variation in tongue movement
- Tongue thrusting
- Fissured tongue
- Patent thyroglossal duct and cyst
- Lingual thyroid
- Median rhomboidal glossitis

Major variations

- Cleft, lobed, bifurcated and tetrafurcated tongue
- Aglossia, hypoglossia and macroglossia
- Hamartoma and dermoid
- Bald and depapillated tongue
- Papillomatous changes

Disorders of lingual mucosa**Changes in tongue papillae**

- Geographic tongue
- Coated or hairy tongue
- Neuromuscular disorders
- Sleep apnea syndrome
- MPDS
- Vascular disorders

Non-keratotic lesion

- Thrush
- White sponge nevus
- Vesiculobullous and other desquamative disorders

Keratotic white lesions

- Lichen planus
- Leukoplakia

Depapillation and atrophic lesions

- Chronic trauma
- Nutritional deficiency
- Hematological abnormalities
- Medication
- Peripheral vascular disease
- Diabetes and chronic candidiasis
- Tertiary syphilis and interstitial glossitis

Pigmentation

- Ulcer and infectious disease
- Superficial vascular disease

Disorders affecting body of mandible

- Amyloidosis
- Infection

Tumors of tongue

- Squamous cell carcinoma
- Benign

Table 22-3: Classification of tongue disorders

Congenital and developmental disorders

- Aglossia and microglossia
- Macroglossia
- Ankyloglossia
- Cleft tongue
- Ankyloglossum superius syndrome
- Lingual varices
- Lingual thyroid nodule
- Variations in tongue movement
- Patent thyroglossal duct cyst
- Tongue thrusting
- Lingual polyp
- Reactive lymphoid aggregate
- Lingual cyst

Local tongue disorders

- Fissured tongue
- Median rhomboidal glossitis
- Benign migratory glossitis
- Hairy tongue
- Crenated tongue
- Foliate papillitis
- Leukokeratosis nicotine glossitis

Depapillation of tongue**Local disease**

- Eosinophilic granuloma
- Traumatic injuries
- Lesions due to automutilation
- Allergic stomatitis
- Facial hemiatrophy
- Cranial arteritis
- Chronic candidiasis

Systemic disease

- Iron deficiency anemia
- Plummer-Vinson's syndrome
- Pernicious anemia
- Niacin deficiency
- Folic acid deficiency
- Peripheral vascular disease

- Dermatomyositis
- Diabetes
- Syphilis
- Zoster infection
- Tuberculosis

Neurological disease

- Glossodynia
- Dyskinesia
- Paralysis
- Oropharyngeal dysphagia

Cyst

- Anterior median lingual cyst
- Bronchogenic cyst
- Epidermoid and dermoid cyst
- Gastric mucosal cyst
- Parasitic cyst
- Thyroglossal duct cyst

Benign tumor

- Fibroma
- Glomus tumor
- Granular cell tumor
- Leiomyoma
- Rhabdomyoma
- Plasmacytoma

Pre-malignant lesion and conditions

- Leukoplakia
- Lichen planus
- Oral submucous fibrosis

Malignant tumor

- Squamous cell carcinoma
- Malignant lymphoma
- Malignant melanoma
- Metastatic tumor
- Sarcoma

Miscellaneous

- Pigmentation of tongue
- Phlebotasia

Macroglossia

Macroglossia is tongue enlargement, which leads to functional and cosmetic problems. Although, this is relatively uncommon disorder, it may cause significant morbidity. Normal speech and swallowing reflexes require normal tongue anatomy and its functions. Swallowing begins as the tongue mixes food with saliva to form a food bolus, which is then propelled into the pharynx by the tongue. Articulation also depends on the tongue's ability to alter the impedance of air and change the resonant characteristics of the upper airway. In macroglossia, increased tongue bulk may impair these functions.

Classification

- *Congenital*
- *Acquired*
 - *Hypertrophic*—in it, muscles of the tongue are hypertrophic. It usually occurs in mentally retarded patients.
 - *Inflammatory*—it may involve the tongue partially or completely. It is due to various causes like syphilitic, Ludwig's angina, etc.
 - *Neoplastic*—it can be based on benign and malignant tumors.
- *Relative macroglossia*—it is a condition, in which a normal sized tongue appears abnormally large, if it is particularly enclosed within a small oral cavity.
- *Apparent macroglossia*—it is a condition where the tongue appears large due to poor muscular control of the tongue, although there is no increase in the bulk of tongue tissue.

Etiology

- *Congenital*—it includes hemangioma, lymphangioma and lingual thyroid. Other congenital disorders which can cause macroglossia are cretinism, Down syndrome, neurofibromatosis and multiple endocrine neoplasia type 2B
- *Inflammatory*—inflammatory causes include tuberculosis, actinomycosis, dental infection, syphilitic gumma, Riga disease, ranula and sublingual calculus.
- *Traumatic*—traumatic causes include dental irritation, hematoma and postoperative edema.
- *Neoplastic*—the neoplastic causes can be divided into malignant and benign lesions; with the malignant lesions including carcinoma and sarcoma. The benign lesions include granular cell tumor, neurofibroma, leiomyoma and lipoma.
- *Metabolic*—metabolic causes are myxedema, amyloidosis, lipid proteinosis, chronic steroid therapy and acromegaly.
- *Muscular hypertrophy*—over development of musculature, this may or may not be associated with generalized muscular hypertrophy or hemihypertrophy.

Fig. 22-1: Macroglossia showing protruded tongue.

Clinical Features

- *Age*—macroglossia is most prominent in infants, but tongue size may remain above normal in childhood and adolescence. As hyoid descends with age, macroglossia may improve.
- *Symptoms*—patient complaint of noisy breathing, drooling of saliva and difficulty in eating. Patient may get recurrent upper respiratory tract infection as tongue is usually protruded (Fig. 22-1) and mucosal drying occurs. The enlargement is generalized and may cause variety of difficulties with speech, feeding and airway problems.
- *Signs*—It may produce displacement of teeth and malocclusion, due to the strength of muscles involved and pressure exerted by the tongue on teeth.
- *Crenated lateral border*—crenation or scalloping of the lateral borders of the tongue; the tips of scalloping fit into the interproximal spaces between the teeth.
- *Syndrome associated*—it is associated with syndromes like Beckwith's hypoglycemic syndrome which includes neonatal hypoglycemia, mild microcephaly, umbilical hernia, and fetal visceromegaly and postnatal somatic gigantism.

Diagnosis

- *Clinical diagnosis*—large size of the tongue can be clinically diagnosed.

Management

- *Orofacial therapy*—it uses a palatal device to stimulate muscular tone and proper tongue position.
- *Surgical management*—majority of the cases of macroglossia are treated surgically. Indications for surgery include airway obstruction, speech difficulties, dysphagia and cosmetics. The procedure of choice is partial glossectomy. Surgical goal is to reduce the tongue size and thus improve the condition.

- *Removal of cause*—removal of primary cause should be done.
- *Orthodontic treatment*—correction of the dental arch deformity and malocclusion by orthodontic treatment.
- *Speech therapy*—correction of defective articulation by speech therapy.

Ankyloglossia

It is also called as 'tongue-tie'. It occurs due to incomplete degeneration of cells while the body of tongue is freed. In it, tip of tongue remains tied to floor of mouth. It is a condition in which the lingual frenulum is either too short or anteriorly placed limiting the mobility of the tongue. Reports of partial ankyloglossia affecting several generations, suggest a possible genetic basis for the minor variation in the attachment of the genioglossus muscle. It may be traumatic or congenital.

Types

- *Complete*—fusion of tongue and the floor of mouth.
- *Partial*—short lingual frenum.

Clinical Features

- *Symptoms*
 - *Restricted tongue movement*—it may limit the movement of the tongue.
 - *Feeding problems*—In extreme cases of ankyloglossia, nursing and feeding problems can occur. Poor sucking and inability to chew some food also occurs.
 - *Speech defect*—it was felt that tongue-tie was associated with speech abnormalities, especially lisping and inability to pronounce certain sounds and words viz t, d, n, l, as, ta, te, time etc.
 - *Tongue biting*—in some cases, recurrent tongue biting is also reported.
- *Signs*
 - *V shaped notch*—when there is an attempt to stick the tongue out, there may be a V shaped notch at the tip (Fig. 22-2). Physical examination will easily demonstrate the short or anteriorly placed lingual frenulum (Fig. 22-3).
 - *Anterior open bite*—patients have midline mandibular diastema and inability to clean the teeth and lick the lips with tongue.
 - *Periodontal problems*—due to high frenum attachment some patient may face periodontal problems.
- *Syndromes associated*—ankyloglossum superius syndrome, Rainbow syndrome, Fraser's syndrome and orofacial digital syndrome.

Diagnosis

- *Clinical diagnosis*—it can be easily diagnosed clinically.

Fig. 22-2: V shaped notch seen at the tip of tongue in patient with tongue-tie.

Fig. 22-3: Anteriorly placed lingual frenum seen in patient of tongue-tie (Courtesy Dr Chole).

Management

- *Counselling*—physician education, parental education and reassurance should be given to the patient.
- *Surgery*—indications for surgery, i.e. frenectomy are as follows:
 - If complete fusion of tongue is present then it requires surgery.
 - When nursing and feeding become a problem, surgery is indicated.
 - Children between 2-4 years, with poor development of speech and anxious parent's desire for the necessary treatment.
 - In cases where tongue-tie has recurred after snipping.
- *Complications of surgery*
 - Injudicious cutting of the frenum in a newborn can cause hemorrhage and the tongue may become too mobile and may be swallowed, causing asphyxia.

- There is also possibility of a subsequent infection at the base of the tongue, with formation of large ulcer and spreading stomatitis.

Cleft Tongue

It is also called as '*bifid tongue*'. It is the condition in which there is cleavage of the tongue due to lack of fusion of the lateral halves.

Pathogenesis

- *Failure of merging*—there is failure of merging of two lateral lingual swelling. Underlying mesenchymal proliferation fails to obliterate the groove. As these masses grow anteriorly, they move apart.

Clinical Features

- *Incidence*—completely bifid or cleft tongue is rare. It is due to lack of merging of lateral swellings of the organ.
- *Appearance*—partially cleft tongue is manifested as deep grooves in the midline of dorsal surface (**Fig. 22-4**).
- *Symptoms*—food debris and microorganisms may collect in the base of cleft and cause irritation.
- *Syndromes associated*—seen with orofacial-digital syndrome, with thick fibrous bands in lower anterior mucobuccal fold, which eliminate the sulcus and is associated with clefting of hypoplastic mandibular alveolar process.

Fig. 22-4: Partially cleft tongue manifested as deep groove in the tongue.

Diagnosis

- *Clinical diagnosis*—cleft can be seen clinically.

Management

- Regular cleaning of the tongue should be carried out.

Ankyloglossum Superius Syndrome

It is characterized by the attachment of the tongue to the hard palate and by limb malformation. It is also caused by genetic and intrauterine environmental factors.

It is a very rare disorder and is associated with jejunal and ileal atresias. Patient has difficulty in speech and mastication. Patient may have difficulty in swallowing. Surgical separation of the tongue from the palate.

Lingual Varices

A varix is a dilated, tortuous vessel (**Fig. 22-5**), most commonly a vein, which is subjected to increased hydrostatic pressure and is poorly supported by the surrounding tissues. Varices involving the lingual veins are relatively common, appearing as red or purple shot-like clusters of vessels on the ventral surface and lateral borders of the tongue as well as in the floor of the mouth. There appears to be no significant relationship between the presence of leg varicosities and sublingual varices.

Fig. 22-5: Tortuous vessels seen on ventral surface of tongue.

Lingual Thyroid Nodule

Presence of thyroid tissue in any region other than normal is called as ectopic thyroid gland. It is rare congenital anomaly which results from failure of descent of the primitive thyroid from the foramina caecum.

Pathogenesis

- *Development of thyroid gland*—the thyroid gland develops in the embryo from the ventral floor of the pharynx, by means of an ectodermal invagination of diverticulum. The thyroid gland tissues are formed at the median end of the two mandibular arches which are separated by tuberculum impar.

- *Development of tongue*—the tongue forms at the same time from this pharyngeal floor and are anatomically associated with thyroid gland by connection through the thyroglossal tract, the lingual remnant of which is known as the foramen caecum.
- *Development of lingual thyroid*—in some cases, thyroid gland fails to descent which gives rise to lingual thyroid. Thus, follicles of thyroid tissue are found in the substance of the tongue.

Clinical Features

- *Age and sex distribution*—females are more affected as compared to males in a ratio of 7:1. The reason for occurrence in female is due to hormonal influence. The age of onset ranges from birth to the 6th decade, with a peak in the 2nd decade.
- *Site*—base of the tongue is the most common site of undescended thyroid gland. It is present in midline.
- *Symptoms*—there may be complaints of dysphagia (difficulty in eating), dysphonia (difficulty in speaking), dyspnea (difficulty in breathing), hemorrhage with pain or feeling of tightness or fullness in the throat. In some cases pain may be referred to ear.
- *Appearance*—it is manifested as a nodular mass in or near the base of the tongue (**Fig. 22-6**), in general vicinity of the foramen caecum. It is often but not always, in the midline.
- *Signs*—the mucosa covering the swelling is thin, smooth and with prominent vascular marking.

Fig. 22-6: Lingual thyroid nodule seen as mass on tongue.

Radiological Features

- *Scintigraphy*—Scintigraphy with ^{131}I and ^{99}Tc can be useful to locate normal and ectopic thyroid tissue. Thyroid radioactive uptake can be determined after administration of ^{131}I .
- *Computed tomography*—it is useful to locate the lingual thyroid. As lingual thyroid nodule contains iodine no contrast agent is used to locate lingual thyroid.
- *Ultrasound*—ultrasound of neck is used to detect lingual thyroid. Doppler ultrasound can also be used. Doppler ultrasound reveals low resistance arterial blood flow.

Diagnosis

- *Clinical diagnosis*—mass seen in vicinity of foramina will give clue to the diagnosis.
- *Radiological diagnosis*—Scintigraphy with iodine will locate the lingual thyroid nodules.

Management

- *Suppressive thyroxin*—suppressive thyroxin should be given for 6 months. This will reduce the size of swelling.
- *Surgical excision*—when it causes difficulty to the patient in spite of thyroxin therapy, excision or ablation with radioiodine is indicated.
- *Surgical excision with reimplantation*—when thyroid gland is absent in the neck, surgical excision with reimplantation can be carried out.
- *Laser*—it can be used as an alternative to scalpel surgery.

Variations in Tongue Movement

- *Curling of tongue*—ability to curl up the lateral borders of the tongue into a tube is noted in 65% of Caucasians and is inherited as an autosomal dominant trait.
- *Folding back tip of tongue*—ability to fold back the tip of the extended tongue, without the aid of the teeth.
- *Trefoil tongue*—clover leaf pattern.
- *Gorlin sign*—extensibility of the tongue, both, forward to touch the tip of nose and backwards into the pharynx.

Tongue Thrusting

Positioning of tongue between the anterior teeth during swallowing, speaking or at rest. It is an infantile swallowing pattern. It may be associated with macroglossia. In these cases, anterior open bite is present.

Patent Thyroglossal Duct Cyst

Development

- *Development of thyroid gland*—thyroid gland develops from an analogue of endothelial cells in the midline of the floor of pharynx, between the first and second branchial arches, just posterior to tubercular impar.
- *Proliferation of cells*—these cells sink into the base of developing tongue descend into the neck and proliferate below the larynx to form thyroid gland.

- *Formation of cyst*—remnants of this part are referred to as thyroglossal duct. Cystic degeneration of it is called as duct cyst.

Clinical Features

- *Age and sex*—it usually occurs in young persons with no sex predilection.
- *Site*—it is seen above the thyroid, in vicinity of the hyoid bone, in midline of the neck.
- *Symptoms*—in some cases, dysphagia may occur.
- *Signs*—it is a firm cystic mass in which formation of fistula may take place. It is compressible.
- *Aspiration*—it yields yellow fluid on aspiration.

Diagnosis

- *Clinical diagnosis*—dysphagia with firm cystic mass in midline of neck will give clue to the diagnosis.
- *Laboratory diagnosis*—the cyst is lined by columnar, respiratory or stratified squamous epithelium. Follicle of thyroid is frequently located in juxtaposition to the cyst lining.

Management

- *Surgical*—it should be surgically excised or enucleated.

Reactive Lymphoid Aggregate

The lingual tonsils, one of the largest oral lymphoid aggregates, are located on the posterior portion of the tongue on the dorsolateral aspect. They are reported to occur on the gingiva, buccal mucosa, tongue and floor of mouth.

Lingual Cyst

It is a rare lesion, located anteriorly in the midline of the tongue (**Fig. 22-7**). It is movable and compressible. It arises as a result of epithelial entrapment during fissural closure of the lateral lingual processes. Surgical excision is recommended.

Local Tongue Disorders

Fissured Tongue

It is also called as '*scrotal tongue*', '*plicated tongue*' and '*lingua dissecta*'.

In this condition tongue with or without a central fissure shows parallel fissures lateral to the midline or fissures at right angle to the long axis of the tongue. A tongue is characterized by furrows, one extending anteroposteriorly and others laterally over the entire anterior surface.

Fig. 22-7: Large lingual cyst of newborn present in the midline of tongue.

Types

- Foliate
- Cribriform
- Plicated.

Etiology

- *Genetic*—fissured tongue is noticed in the generation.
- *Psychological*—it is seen in mentally retarded and psychotic individuals.
- *Trauma*—chronic trauma can lead to fissured tongue.
- *Nutritional deficiency*—in some cases of vitamin deficiency, fissured tongue can occur.

Clinical Features

- *Age*—it can be seen at any age. Number, width and depth of fissures are increased with age in the affected individual.
- *Symptoms*—it is usually painless, except in some occasional cases in which food debris tends to collect in the groove and produce irritation.
- *Appearance*—it is manifested as small furrows or grooves on the dorsal surface, often radiating out from the central groove along the midline of the tongue (**Fig. 22-8**).
- *Pattern*—six different patterns of tongue fissuring were observed, i.e. plication, central longitudinal fissuring (**Fig. 22-9**), double fissures, and transverse fissuring arising from a central fissure, transverse fissuring with a central fissure and lateral longitudinal fissuring (**Fig. 22-10**).
- *Syndrome*—it is associated with Melkersson-Rosenthal syndrome which includes cheilitis granulomatosa, facial paralysis, fissured tongue and non-pitting, non-inflammatory painless edema of face.

Fig. 22-8: Fissured tongue manifested as furrow radiating from the midline.

Fig. 22-9: Central longitudinal fissure seen in fissure tongue (Courtesy Dr Chole).

Fig. 22-10: Lateral longitudinal fissure seen in fissure tongue (Courtesy Dr Chole).

Diagnosis

- *Clinical diagnosis*—fissure can be easily diagnosed on clinical examination.

Management

- *Maintenance of tongue hygiene*—you have to clean the debris with brush.

Median Rhomboid Glossitis

It is also called as '*central papillary atrophy of tongue*'. It is a developmental defect resulting from an incomplete descent of tuberculum impar and entrapment of a portion between fusing lateral halves of the tongue. It is a benign lesion of the tongue, characterized by rhomboid or oval in shape, changes occur in the tongue mucosa in the midline, just anterior to the foramen caecum (Fig. 22-11).

Fig. 22-11: Rhomboidal shaped lesion seen in tongue (Courtesy Dr Chole).

Pathogenesis

- *Failure of tuberculum impar*—it is a congenital abnormality of the tongue which is due to failure of tuberculum impar to retract or withdraw before fusion of lateral halves of the tongue, so that a structure devoid of papilla is interposed between it.

Etiology

- *Developmental*—the persistent tuberculum impar suggests its developmental origin.
- *Fungal infection*—*Candida albicans* is many times found in this lesion. This type of lesion is called as *posterior midline atrophy candidiasis*.
- *Metabolic*—median rhomboid glossitis is more common in a diabetic than in non-diabetic subjects.

Clinical Features

- *Age and sex*—males predominate over females (3:1). It is common in adults with age ranging from 15 to 84 years.
- *Site*—it is located just anterior to the foramen caecum on dorsal surface of the tongue, in midline and anterior to the circumvallate papillae.
- *Symptoms*—generally asymptomatic, but pain and ulceration are reported. Rest of the tongue may be coated or matted.
- *Appearance*—it appears as an ovoid, diamond or rhomboidal shaped reddish patch or plaque on the dorsal surface of the tongue, immediately anterior to the circumvallate papillae (**Fig. 22-12**). In some cases, flat or slightly raised area stands out from rest of the tongue because it has no filiform papillae.
- *Surface*—the surface is dusky red and completely devoid of filiform papillae and usually smooth. The texture may be varied from a reddish, smooth, granular surface to a lobulated and indurated surface.
- *Kissing lesion*—soft palate erythema may be seen where the lesion of median rhomboidal glossitis touch the palate.

Fig. 22-12: Median rhomboid glossitis
(Courtesy Dr Amit Parate).

Diagnosis

- *Clinical diagnosis*—rhomboidal shaped lesion seen in posterior part of tongue will diagnose the lesion.
- *Laboratory diagnosis*—biopsy shows loss of papillae with varying degrees of hyperparakeratosis. There is proliferation of spinous layer with elongation of rete pegs, which may branch and anastomose.

Management

- *Antifungal agents*—if candidal organism is found, it is treated with an antifungal agent.
- *Long standing cases*—only in long standing cases, cryosurgery or an excisional biopsy is indicated.

Benign Migratory Glossitis

It is also called as 'geographic tongue', 'wandering rash', 'glossitis areata exfoliativa', and 'erythema migrans'.

It refers to irregularly shaped reddish areas of depapillation and thinning of dorsal tongue epithelium which is surrounded by a narrow zone of regenerating papillae that are whiter than the surrounding tongue surface.

Etiology

- *Hypersensitive patient*—in patients with geographic tongue, there is a high frequency of history of asthma, eczema and hay fever.
- *Other factors*—geographic tongue can be seen in immunological reaction, emotional stress, hereditary factors, infections, and nutritional deficiencies.

Classification

- *Type I*—lesion confined to the tongue, with both active and remission phases. No other lesion elsewhere in the oral cavity.
- *Type II*—as type one with similar lesions elsewhere in the mouth.
- *Type III*—lesions on the tongue are not typical and may be accompanied by lesions elsewhere in the mouth. It consists of two forms:
 - *Fixed form*—a few areas of the tongue are affected, but no movement is observed. They may disappear only to recur at the same area.
 - *Abortive forms*—this form starts as yellow-white patches, but disappear before acquiring the typical appearance of geographic tongue.
- *Type IV*—no tongue lesions are present, but geographic areas present elsewhere in the mouth.

Clinical Features

- *Age and sex*—it is common in young and middle aged adults, with an age range of 5 to 84 years with a predilection for females.
- *Site*—lesion confines to dorsal surface (**Fig. 22-13**) and lateral border of the tongue, but may occur on the ventral surface.
- *Size*—it is extremely variable in size and diameter and it may be single or multiple (**Fig. 22-14**).

Fig. 22-13: Geographic tongue seen on dorsal surface of tongue (Courtesy Dr Parate).

Fig. 22-15: Multiple area of desquamation surrounded by yellowish white line (Courtesy Dr Parate).

Fig. 22-14: Multiple area of erythema seen in geographic tongue.

Fig. 22-16: Geographic tongue elevated fungiform papillae.

- **Symptoms**—it is asymptomatic, but the patient may complain of burning sensation that is made worse by spicy or citrus food.
- **Appearance**—initially appears as a small erythematous, non-indurated, atrophic lesion, bordered by a slightly elevated distinct rim that varies from gray to white to light yellow.
- **Color**—loss of filiform papillae produces pink to red smooth shiny surface except the residual fungiform papillae.
- **Signs**—Multiple areas of desquamation of filiform papillae, in an irregular circinate fashion are seen. Central portion or lesion, sometimes appears inflamed, while the border is outlined by thin yellowish white line or band (**Fig. 22-15**).
- **Fungiform papillae**—fungiform papillae persist in the desquamated areas as small elevated red rods (**Fig. 22-16**).
- **Migration**—area of desquamation remains for a short time in one location and then heals and appears in another location thus giving rise to the term 'migration'.
- **Prognosis**—condition may persist for weeks or months and then regress spontaneously only to recur at a later date.
- **Ectopic geographic tongue**—lesion is not always restricted to tongue and similar irregular or circinate lesions occur elsewhere in oral cavity and are called as *ectopic geographic tongue* or *erythema circinate migrans* or *annulus migrans*.

Diagnosis

- **Clinical diagnosis**—multiple areas of desquamation on dorsal surface of tongue.
- **Laboratory diagnosis**—biopsy shows loss of filiform papillae with hyperparakeratosis and acanthosis. There is also presence of *Monro's abscess*, near the surface.

Differential Diagnosis

- *Psoriasis*—in it, skin lesions are present.
- *Reiter's syndrome*—skin, ocular and urethral lesions occur with arthritis.
- *Pityriasis rosea*—skin lesions present.
- *Lichen planus*—absence of raised whitish yellow rim.
- *Use of strong mouth wash*—history.
- *Anemic condition*—hematological study and absence of raised yellowish white border.

Management

- *For control of burning*—topical local anesthetic agents like lidocaine, dyclonine hydrochloride or diphenhydramine can be given.
- *Other*—bland diet, elimination of irritants and psychological reassurance is useful.
- *Topical therapy*—topical corticosteroids and topical application of salicylic acid and tretinoin (retinoic acid or Vit A) for external use.
- *Zinc supplement*—recent study suggests that zinc supplement is effective in symptomatic geographic tongue.

Hairy Tongue

It is also called as '*lingua villosa, lingua nigra, black hairy tongue*'. It designates an overgrowth of the filiform papillae on the dorsum of the tongue, giving the tongue a superficial resemblance as that of hairiness. There is marked accumulation of keratin on the filiform papillae of the dorsal tongue. There may be delayed shedding of the horny layer of the filiform papillae or there may be an increase in the rate of formation of keratin.

Etiology

- *Fungal and bacterial overgrowth*—overgrowth of fungal organisms like *Candida albicans* and certain bacterial organism can lead to hairy tongue.
- *Use of certain drugs*—oral use of certain drugs (sodium perborate, sodium peroxide and antibiotics like penicillin and Aureomycin).
- *Radiation*—extensive X-ray radiation around head and neck for the treatment of tumors.
- *Poor oral hygiene*—Patients who are unable to maintain oral hygiene can lead to accumulation of keratin in the tongue.
- *After surgery*—it also occurs in patient with intermaxillary fixation and with disturbed orophysiology, due to recent surgery in the oral cavity.
- *Lowered pH*—a lowered pH of oral secretion, which blocks the normal desquamation of epithelial cells covering the filiform papillae.

- *Debilitating diseases*—when the tongue movement is limited by some illness.
- *Foods*—various foods, particularly coffee and tea, probably contribute to the diffuse coloration.

Clinical Features

- *Site*—the lesion involves the dorsum, particularly the middle and posterior one-third.
- *Symptoms*—papillae which are of considerable length will occasionally brush the palate and may produce gagging or bad taste.
- *Signs*—there is hypertrophy of filiform papillae. The papillae may reach a length of 2 cm. Papillae can be elevated by using dental instrument.
- *Appearance*—the elongated papillae have an appearance of hair. The hyperplastic papillae then become pigmented by the colonization of chromogenic bacteria, which can impart a variety of colors ranging from green to brown to black to yellow. This gives it a coated or hairy appearance and retains debris and pigments from substances such as food, tobacco, smoke and candy. Color can be imparted by tobacco, certain food and medicines.
- *Earthy or encrusted tongue*—extreme degree of coating occurring in dehydrated, debilitated and terminally ill patient can lead to a very thick, leathery coating on the tongue which is referred to as 'earthy' or 'encrusted' tongue. It is heavily coated with bacteria and fungi and forms a thickened malted layer.

Diagnosis

- *Clinical diagnosis*—hyperplastic papillae with green to brown color will give clue to the diagnosis.
- *Laboratory diagnosis*—there is elongated papillae with mild hyperkeratosis and inflammatory cells.

Management

- *Maintenance of tongue hygiene*—brushing of the tongue twice daily for 2 minutes, making gentle movements over the involved area towards the tip of the tongue.
- *Elimination of predisposing factors*—all the predisposing factors which are responsible for hairy tongue should be eliminated.
- *Topical keratolytic application*—the topical application of keratolytic agent such as podophyllum in acetone and alcohol suspension seems to be quite effective. It will produce desquamation of hyperkeratotic papillae.

Crenated Tongue

The term is applied to a condition in which indentations of teeth are observed at the lateral margins of the tongue. It

may occur due to abnormal tongue pressure habits and tongue thrusting habits. Any enlargement of the tongue may cause indentations on the teeth.

Often, impression of teeth is seen on the tongue. It is usually an asymptomatic and harmless condition.

Foliate Papillitis

One foliate papilla is present in newborn at each side of the tongue, consisting of 4 to 8 leaves and located at the junction of the anterior two-thirds of the tongue and the base. The folds are separated by grooves of different depths, perpendicular to the longitudinal axis of the tongue. In adults, they are barely noticeable, but sometimes it may swell.

Hypertrophy of lymphoid tissue may be followed by secondary traumatization resulting in so called foliate papillitis.

Clinical Features

- *Age and sex distribution*—it is more common in women, usually in the second half of life.
- *Symptoms*—symptoms may be partly due to upper respiratory tract infection and partly due to irritation. Soreness, tenderness, pain and occasionally, a sour or metallic taste.
- *Location*—the condition may be bilateral with a duration varying from few weeks to many years.
- *Signs*—foliate papillae frequently become inflamed and enlarged, so that it is clinically evident (**Fig. 22-17**).

Fig. 22-17: Foliate papillitis showing inflammation in anterior part of tongue.

Diagnosis

- *Clinical diagnosis*—inflamed and enlarged foliate papillae with pain will aid in diagnosis.

Management

- *Elimination of irritating factors*—it consists of elimination of irritating factors such as sharp edges of teeth and dentures.

Leukokeratosis Nicotina Glossi

It is also called as 'smoker's tongue'. It is homogenous, like leukoplakia with evenly distributed, pinpoint, hemispherical depressions, showing so called golf ball appearance. As a result of heavy smoking, there is loss of papillae. No other clinical features are found in these patients.

Depapillation of the Tongue

Local Causes

- *Eosinophilic granuloma*—it is not related with eosinophilic granuloma of bone. It is also called as 'ulcerated granuloma eosinophilicum diutinum', 'traumatic granuloma' or 'reparative lesion'. The cause of the lesion is unknown. It is characterized by a well demarcated proliferative ulceration covered by thick masses of fibrin and detritus.
 - *Age and sex*—it may occur at any age and does not show a sex predilection.
 - *Site*—it is located on the dorsum, margin or inferior surface of the tongue. Some of the cases are also found on labial mucosa, floor of the mouth, alveolar ridge and gingiva.
 - *Appearance*—the lesions are ulcerative, not indurated and rather well circumscribed.
 - *Symptoms*—there is putrid odor.
 - *Signs*—the ulceration is probably due to moist environment and frequent traumatization. It can be confused with squamous cell carcinoma.
 - *Management*—when one is dealing with an eosinophilic granuloma, spontaneous healing can be expected in a matter of weeks.
- *Traumatic injuries*—the tongue may be repeatedly traumatized, either mechanically or chemically. Trauma is associated with jagged teeth, rough margins of restorations and inadvertent contact of tongue with dental medicaments such as phenol and eugenol. There is localized area of depapillation with papillary regeneration present. A sharp edge of the tooth may cause a yellowish, not indurated and well circumscribed ulcer at the borders of the tongue. Severe damage of the tongue may occur during epileptic seizures. Prolonged oral intubation may cause a large permanent cleft of the tongue. Cotton roll ulcers are rare, but may occur on the borders of the tongue. Such ulcers are not indurated and can be extremely painful.
- *Lesion due to automutilation*—injuries to the tongue can occur due to self inflicted bites. It usually occurs in mentally handicapped persons.
- *Allergic stomatitis*—it refers to edematous changes in part or all of the oral and lingual mucosa, due to

hypersensitivity reaction. It can occur due to certain drugs like antibiotics, cancer chemotherapeutic agent and anticholinergic agents. It can also occur due to variety of allergens such as monomer of the denture, mouthwashes, chewing gum and lipstick. There is edematous swelling of the tongue. There is depapillation of the tongue (**Fig. 22-18**).

Fig. 22-18: Depapillation of tongue is caused due to allergy.

- *Facial hemiatrophy*—it is characterized by unilateral atrophy of the skin, subcutaneous tissues and muscle of the face. There is atrophy of half of the tongue.
- *Cranial arteritis*—rheumatic polymyalgia and temporal arteritis is an inflammatory condition of large and median sized arteries in elderly persons. There is no sex predilection. Symptoms include headache, fever, sweating, malaise, fatigue, anorexia and weight loss. Blindness is the most severe complication. Several cases of painful ulceration and gangrene of the tongue, as a result of arteritis, have been reported. Lingual pain and intermittent blanching of the tongue also has been described. Early use of adequate corticosteroid therapy at the level of 40 to 60 mg daily is required for the treatment of suspected cranial arteritis.
- *Chronic candidiasis*—chronic atrophic candidiasis can be present on the dorsum of the tongue (**Fig. 22-19**). It is difficult to distinguish it from median rhomboidal glossitis. It is diagnosed by scraping and cytological examination.

Systemic Disease

- *Iron deficiency anemia*—inhibition of epithelial reproduction, secondary candidiasis and chronic xerostomia. There are atrophic changes on the dorsum of the tongue (**Fig. 22-20**). It first appears at the tip and lateral borders with loss of filiform papilla. In extreme cases, the entire

Fig. 22-19: Chronic atrophic candidiasis causing depapillation of tongue.

Fig. 22-20: Depapillation of tongue seen in anemia.

dorsum becomes smooth and glazed. The tongue may be very painful and is either pale or fiery red.

- *Plummer Vinson syndrome*—sideropenic anemia shares atrophic glossitis, angular cheilitis, generalized atrophic oral mucosa, oral ulceration and secondary candidiasis. The tongue may be red or pale, painful and fissured. There is also dysphagia and dystrophy of nails.
- *Pernicious anemia*—the patient suffer from general weakness, burning or itching sensation from the oral mucous membrane with disturbance of taste and occasional dryness of mouth. There may be paresthesia, atrophy of filiform and fungiform papillae. In advanced cases, dorsum of the tongue becomes completely atrophic, smooth and fiery red surface. Tongue appears flabby because the normal muscle tonus is reduced.
- *Niacin deficiency*—deficiency of niacin results in a disease called as 'pellagra'. The tongue become fiery red and

devoid of papillae. The filiform papillae are the most sensitive and disappear first. The fungiform papilla may become enlarged. In advanced cases, all the papillae are lost and reddening become intense. In this, tongue may become so swollen that indentation from teeth are found along borders of the tongue.

- *Folic acid deficiency*—there is marked glossitis. The tongue is fiery red and atrophy filiform and fungiform papillae. The tongue is often swollen and small cracks may appear on the dorsum of the tongue.
- *Scleroderma*—fibrosis of submucosal tissue secondary to the obliteration of small vessels by an autoimmune process is responsible for a scarred, shrunken and atrophic appearance of the tongue in scleroderma. In scleroderma the tongue shrinks, losing its mobility and papillary pattern. The color of tongue changes to a vivid appearance due to circulatory disturbances. In the end stages, the tongue lies as a stiff, reduced body in the floor of mouth.
- *Lupus erythematosus*—isolated irregular areas of lingual mucosa, atrophy and ulceration caused by arteritis, are seen in lupus erythematosus.
- *Dermatomyositis*—it is a clinical syndrome consisting of polymyositis associated with skin lesions. The oral mucosa may show dark red or bluish erythema. In the early stages, tongue is markedly swollen and later becomes harder. In the late phase, tongue is atrophic.
- *Diabetes*—decreased nutritional status of the lingual papillae, as a result of vascular changes affecting sub-papillary dorsal capillary plexus supplying it, causes atrophic glossitis. Central papillary atrophy of the dorsum in which low flat papillae are noticed just anterior to the row of circumvallate papillae, is associated with diabetes.
- *Syphilis*—depapillation of the tongue usually occurs in secondary and tertiary syphilis. In secondary syphilis mucus patch occur, which may be single or multiple on the tongue. Tongue in tertiary syphilis may show gumma formation. A more diffuse, chronic, non-ulcerating, irregular induration, with an asymmetrical pattern of grooves and smooth atrophic field covering the entire dorsum is seen. Gumma is often developed in chronic interstitial glossitis. There is atrophy of filiform and fungiform papillae.
- *Zoster infection*—it is a viral infection caused by herpes zoster virus. Numerous vesicles occur on the ventral surface of the tongue.
- *Tuberculosis*—the most frequent involved area is dorsum of the tongue. There is ulceration with irregular outline and undermined borders, covered by yellowish gray fibrinous layer. There is usually pain associated with ulceration.

Neurological Disorders

Glossodynia

Terminology

- *Glossalgia*—the term glossalgia is used to describe painful tongue.
- *Glossopyrosis*—the term glossopyrosis is used to describe burning sensation in the tongue.
- *Lingual paresthesia or dysesthesia*—when just discomfort is felt, it is called as lingual paresthesia or dysesthesia.
- *Stomatodynia*—when the entire oral cavity is involved, the terms stomatodynia, stomatopyrosis and oral dysesthesia are used.

Etiology

- *Local factors*
 - *Habits*—oral habits such as excessive use of tobacco, excessive drinking, frequent uncontrolled movements of the tongue or bruxism.
 - *Dental causes*—local dental causes such as dentures, irritating clasps or a recently fixed bridge.
 - *Referred pain*—referred pain from infected teeth or tonsils, Moeller's glossitis and periodontal disease.
 - *Sensitizers*—it may be caused by peppermint oil in sweets (since it is a volatile oil) and primary and secondary sensitizers.
 - *Local tongue disorders*—geographic tongue, plicated tongue, lichen planus and median rhomboidal glossitis.
 - *Electrogalvanic discharge*—electrogalvanic discharge due to dissimilar metallic restoration.
 - *Atherosclerotic changes*—atherosclerotic changes in the lingual arteries have also been a cause for glossodynia.
 - *Allergy*—allergy to denture base material, metallic restoration and particular food, medication, mouth-washes and dentifrices.
- *Systemic factors*—systemic diseases like multiple myeloma, amyloidosis, muscular tension, hypoestrogenism, pernicious anemia, pellagra, diabetes, vitamin B deficiency can cause glossodynia. Gastric disturbances such as hyperacidity or hypoacidity, angioneurotic edema, mercurialism. Prolonged antibiotic therapy, psychological problems, xerostomia, and hypothyroidism may be responsible for glossodynia.
- *Neurological factors*—trigeminal neuralgia, damage of lingual nerve after surgery, glossopharyngeal neuralgia. Cerebrovascular and subclinical cerebrovascular accidents can possibly cause pain in the tongue.

- *Idiopathic*—when no local, systemic or neurological causes can be detected, the term essential or idiopathic can be used. In these circumstances, depression, cancerophobia and neurosis are regarded as the possible causes.

Clinical Features

- *Nature of pain*—the description varies from patient to patient, some refer it as pain and others as burning, tingling or numbness in the tongue. It may occur as an isolated features or it may be one from group of oral symptoms.
- *Changes in tongue*—it may occur with clinically observable changes in tongue or without observable changes.

Management

- *Removal of local cause*—this is best management treatment for glossodynia.
- *Muscle relaxant*—treatment of muscular problems by correction of malocclusion or by muscle relaxants such as diazepam.
- *Management of systemic problems*—treatment of the systemic cause should be done.
- *Surgical*—surgical exploration of glossodynia with neuropathy.
- *Topical treatment*—use of topical analgesics 0.5% of Diphenhydramine alone or mixed with 0.5% of dyclonine or lidocaine.

Dyskinesia

It is defined as an impairment of voluntary motion, causing movements that are incomplete or only partial.

Generalized Neurological Disease

- *Huntington's chorea*—it is a hereditary disease manifesting progressive degeneration of nerve elements and characterized by choreiform hyperkinesia including grimacing of face. The speech may be affected early, due to the involuntary movements of the tongue.
- *Gilles de la Tourette's syndrome*—it is characterized by motor incoordination and tics, with echolalia and coprolalia. The patient exhibits bizarre facial tics, protrusion of the tongue and the tendency for lip licking.
- *Chorea minor*—it is a disease of the childhood, characterized by the occurrence of rapid irregular, aimless involuntary movements of the muscles of the extremities, face and trunk. The tongue is protruded quickly and rapidly withdrawn to prevent biting of the tongue by involuntary movements of the jaw muscle.

Amyotrophic Lateral Sclerosis

- *Mechanism*—it is a chronic progressive disease of an unknown cause characterized by atrophy and fasciculations of the wasted muscle. It involves demyelination of the corticobulbar tracts and degeneration of cranial nerve motor nuclei.
- *Site*—the muscles of palate, pharynx and tongue are commonly affected.
- *Symptoms*—speech may be slurred. Eating solid food and drinking can cause choking.
- *Early stage*—hypoglossal nerve involvement results in flaccidity, symmetric weakness, slowness of movement and atrophy of tongue.
- *Middle stage*—in the middle stage, a gradual and generalized weakening of the tongue occurs. This is accompanied by spasticity, which results in reduced rate, range and force of articulatory tongue movements.
- *Late stage*—in the late stage, there is virtually unintelligible articulation.

Buccolingual Masticatory Syndrome

- This syndrome consists of repetitive, non-rhythmic abnormal movements, that occur at the speed of normal voluntary movements.
- *Spontaneous dyskinesia*—it consists of movement of mandible and protrusion of the tongue or the lips.
- *Tardive dyskinesia*
 - *Vermicular movements*—fine tremors and fasciculations of the tongue are described as 'vermicular movements'.
 - *Fly-catcher's tongue or bon-bon sign*—rapid darting movements of the tongue is 'fly-catcher's tongue or 'bon-bon' sign.
- *Rabbit syndrome*—when bon-bon sign is associated with smacking movement of the lips with constant lip tremor, it is referred as 'rabbit syndrome'.

Paralysis

It is also called as '*glossoplegia*'. It usually occurs due to unilateral injury of the nucleus in the medulla or the peripheral hypoglossal nerve. There is paralysis and atrophy of the muscles of one-half of the tongue.

Causes

It may be caused by acute anterior poliomyelitis, infectious polyneuritis, neurofibromatosis, syringobulbia, irradiation of head and neck and compression by a tortuous internal carotid artery in the neck.

Clinical Features

- *Signs*—the affected tongue deviates towards the paralyzed side when protruded. The movement towards

the normal side is weak or absent. When the tongue lies on the floor of the mouth, it may deviate or curl slightly toward the healthy side (**Fig. 22-21**) and movements of the tongue towards the back of the mouth on the healthy side, are impaired.

- **Appearance**—if the paralysis is not accompanied by atrophy, the tongue may appear to bulge slightly and to be higher and somewhat more voluminous on the paralyzed side. When atrophy supervenes, paralyzed side becomes smaller and the tongue may become curved towards the paralyzed side with sickle shaped deformities.
- **Location**—in some cases, hypoglossal nerve may be affected bilaterally, causing impairment of the tongue, mobility in lateral direction and atrophy of sides of the tongue.
- **Syndromes associated**—it can be seen in Syndromes like Dejerine (anterior bulbar syndrome), Jackson-MacKenzie (vagoaccessory-hypoglossal syndrome), Collet-Sicard, Duchenne, Möbius and Tapia.

Fig. 22-21: Paralysis of tongue presented as deviation of tongue on the affected side.

Oropharyngeal Dysphagia

It is caused by weakness of the tongue. Symptoms are aspiration while swallowing, regurgitation of food into nose, pharyngeal pain on swallowing and inability of the tongue to move the bolus of food into the pharynx. Dilatation or atony of the pyriform sinuses and pharynx with retention of contrast media in the valleculae is the characteristic radiographic findings.

Dysgeusia and Hypogeusia

Dysgeusia is persistent abnormal taste and hypogeusia is diminished taste sensation. No stimulus is required for the altered tastes, it is called as 'phantom' taste.

Causes

- **Local factors**—local factors like oral candidiasis, oral galvanism, periodontitis, oral lichen planus, and xerostomia.
- **Systemic factors**—systemic factors like vitamin deficiency, nutritional deficiency, food allergy, Sjögren syndrome, liver dysfunction, Crohn's disease, depression, alcoholism, temporal arteritis, migraine, upper respiratory tract infection, chronic gastritis and radiation therapy to neck and head may cause dysgeusia.
- **Pharmacological agents**—pharmacological agents like anticoagulant, antihistamine, antihypertensive, antimicrobial, antipsychotic drugs can cause dysgeusia.

Clinical Features

- **Onset**—onset of dysgeusia is sudden and is distinguished promptly by the patient.
- **Symptoms**—patient may told altered taste as metallic, foul, rancid.
- **Stimulus**—stimulus require for altered taste like certain food and liquids.

Management

- **Removal of underlying cause**—if underlying cause is removed, taste function will return to normal.

Premalignant Lesions and Conditions

Leukoplakia

It can occur anywhere in the oral cavity but tongue is the one of the commonest site. If it occurs on the tongue, it is called as 'chronic superficial glossitis'.

Etiological factors are classically known as 6 'S'. They are: Smoking, Syphilis, Sharp tooth, Sepsis, Sprits and Spices.

Clinical Features

- **Site**—it is confined to the anterior 2/3rd of the tongue (**Fig. 22-23**). It gradually spreads on the dorsum.
- **Appearance**—the surface may become fissure and cracked, due to contraction of the underlying scarred tissue by chronic inflammation.
- **Signs**—the affected area of the tongue shows milky-white patches with cracks and fissures (**Fig. 22-22**). In course of time atrophy tends to succeed hypertrophy, the thickened papillae disappear and the white membrane is worn off. The surface becomes smooth and red.

Fig. 22-22: Milky-white patches seen in leukoplakia of tongue.

Fig. 22-23: Leukoplakia seen on ventral surface of tongue.

Clinical Staging of Leukoplakia on the Tongue

- *Stage I*—appearance of thin gray transparent film on the affected part of the tongue. The thin milky film may be widespread.
- *Stage II*—the thin film turns opaque and white. In the beginning it looks soft, but later on cracks and fissures appear.
- *Stage III*—hyperplasia causes small nodules and warty outgrowth. Desquamation also appears simultaneously which leaves areas of smooth red and shiny surface.
- *Stage IV*—it is the stage of appearance of clinically detectable carcinoma. The carcinomatous changes usually occur with the fissure. It should be suspected if there is local thickening, bleeding and pain.

Rests of the lesions are described in the Chapter 12: Oral Pre-malignant Lesions and Conditions and Chapter 11: Keratotic and Non-keratotic Lesions.

Malignant Tumor

Squamous Cell Carcinoma

It is the most common oral carcinoma with 60% cases arising from the anterior 2/3rd of the tongue and remainder from the base. Carcinoma of tongue is caused by physical trauma, alcohol, tobacco smoke, candidiasis, syphilis, sepsis, chronic dental trauma and chronic superficial glossitis.

Clinical Features

- *Age and sex*—carcinoma of the tongue is disease of middle and later decades of life, with mean age at presentation being about 60 years. Males are more commonly affected than females.
- *Site*—the majority of tongue carcinoma occurs on lateral border of anterior 2/3rd of the tongue and undersurface of the tongue (Fig. 22-24). The lesions on the posterior border of the tongue are usually of higher grade malignancy, metastasize earlier and often have a poor prognosis. Cancers located in the anterior 2/3rd of the tongue are detected in early stages, as compared to those in the posterior 1/3rd of the tongue.

Fig. 22-24: Carcinoma of tongue occurring on the under surface area.

- *Symptoms*
 - *Painless mass or ulcer*—the most common presenting signs of carcinoma of tongue is a painless mass or ulcer (Fig. 22-25), although in most patients the lesion ultimately becomes painful, especially when it becomes secondarily infected.
 - *Salivation*—excessive salivation gradually appears along with the growth. In late stages, saliva becomes blood stained.
 - *Foetor oris*—as the patient is unable to swallow saliva, offensive smell in the mouth occurs due to bacterial stomatitis.

Fig. 22-25: Ulceration seen on lateral border of tongue in carcinoma.

- *Sore throat*—there is complaint of sore throat and pain in case of lesions on posterior border of the tongue.
- *Immobility of the tongue*—it occurs due to extensive carcinomatous infiltration of the lingual musculature. It becomes worse when floor of mouth is involved and ultimately, it causes difficulty in speech.
- *Hoarseness of voice and dysphagia*—it is present when the carcinoma involves posterior 3rd with involvement of pharynx and larynx.
- *Signs*—carcinoma of the tongue may be seen in four varieties.
 - *Ulcerative variety*—is usually seen near the edge of the tongue. The ulcer looks irregular and the edges are raised and everted. The floor is covered by yellowish gray slough. Base is indurated.
 - *Warty growth*—it usually possesses a broad and indurated base (**Fig. 22-26**). It is developed on excess proliferating growth of filiform papillae. Rarely, it takes cauliflower type of look.

Fig. 22-26: Warty growth seen in carcinoma of tongue (Courtesy Dr Chole).

- *An indurated plaque or mass*—in this case, a typical indurated submucous plaque can be felt (**Figs 22-27A and B**).
- *A fissure*—it is usually presented as a chronic fissure which does not heal.

Figs 22-27A and B: Induration seen in malignancy of tongue (Courtesy Dr Chole).

- *Progress*—the tumor may begin as a superficially indurated ulcer with a slightly raised border and may proceed either to develop a fungating, exophytic mass or to infiltrate the deep layers of the tongue, producing fixation and induration without much surface changes. At an early stage, tongue cancer may appear as thickened, leucoplakic patches, or as a nodule.
- *Complication*—patient usually dies due to cancerous cachexia, starvation, inhalation bronchopneumonia, asphyxias and hemorrhage from involved cervical lymph nodes.

Spread of Carcinoma

- **Local spread**—it spreads by infiltration and invasion.
 - *Carcinoma of anterior 2/3rd of the tongue*—it usually starts on the lateral margins of the tongue and invades the floor of the mouth early, but it does not extend to the other side across the midline.
 - *Carcinoma of posterior 1/3rd of the tongue*—it tends to spread to the corresponding tonsils, epiglottis and soft palate.
- **Lymphatic spread**
 - *Tip of the tongue*—carcinoma of tip of the tongue may drain to the submental nodes, but may also drain to the juguloomohyoid nodes.
 - *Anterior 2/3rd*—it drains into the submandibular lymph nodes.
 - *Posterior 1/3rd*—it drains into jugulodigastric group of the upper deep cervical nodes on both sides of the neck.
- **Blood**—it is rare and extremely late in occurrence. It is only seen when the growth is in extreme posterior part of the tongue.

Management

- **Surgery**—if the growth is less than 1 cm in diameter, it should be removed along with a wide margin of mucosa, not less than 1 cm. If it is localized to anterior 2/3rd of the tongue, partial glossectomy or subtotal glossectomy should be carried out. When the growth reaches within 2 cm of jaw, hemimandibulectomy may be required with excision of the growth.
- **Radiotherapy**—when the growth is more than 1 cm in diameter in anterior 2/3rd, the preliminary treatment is radiotherapy in the form of interstitial radiotherapy.
- **Prognosis**—the 5 years survival rate of cancer tongue is not more than 25%.

Other malignant tumors of the tongue are rare and are discussed in detail in Chapter 16: Malignant Tumor of Jaw.

Pigmentation of Tongue

The tongue may exhibit various patterns of racial melanin pigmentation (**Figs 22-28A and B**).

Endogenous pigmentation is rarely identifiable on the dorsum of tongue because of the thickness of the epithelium, but jaundice may be apparent under the thinner ventral mucosa.

Exogenous pigmentation of filiform papillae of the normal and coated or hairy tongue is very common and result from microbial growth, metabolic products, food debris and dyes from candy, beverages and mouth rinses.

Pigmentation of the tongue has been described by a commonly used anti-chemotherapeutic agents doxorubicin

Figs 22-28A and B: Pigmentation seen in tongue due to melanin deposit.

hydrochloride, which also discolor patient's urine, nailbeds and skin folds. Extravasation of red cells around lingual varicosities may give patchy, bluish red discoloration. The thin tissue overlying a ranula is said to have a greenish blue appearance.

Classification of Lip Disorders

Developmental

- Congenital lip pits
- Commissural lip pits
- Double lip
- Cleft lip and cleft palate

Cheilitis

- Glandular cheilitis
- Granulomatous cheilitis
- Angular cheilitis
- Contact cheilitis
- Eczematous cheilitis
- Actinic cheilitis
- Exfoliative cheilitis
- Plasma cell cheilitis
- Cheilitis due to drugs

Carcinoma of lip

Miscellaneous

- Chapping of lips
- Actinic elastosis
- Lip ulcers due to caliber persistent artery

Development of Lip

In the sixth week of intrauterine life, two medial nasal processes merge in midline. This will form intermaxillary segment which will give rise to center of upper lip.

In adult, center of upper lip forms *philtrum*. Philtrum is bound laterally by two vertical ridges under the nostril. Lateral part of upper lip fissure presents in maxillary process. This may lead to cleft formation if it is not covered by epithelium and fused. Upper lip is thus formed from one-third medial nasal process and two-third maxillary process.

Anatomy

- *Mucocutaneous junction*—lips are fleshy folds lined by skin externally and mucous membrane internally. The upper and lower lips close along the red margin which represents the *mucocutaneous junction*.
- *Surface*—the lips are covered with skin on the external surface and mucous membrane on the inner surface, which has profuse salivary glands.
- *Extent*—the lip extends from the lower end of the nose to the upper end of the chin.
- *Nasolabial groove*—the upper lip borders onto the nose and is separated from the cheek by a variably deep groove called as *nasolabial groove*.
- *Lower lip*—the lower lip is separated from the chin proper by a more or less sharp and deep groove that is convex superiorly called as *labiomental groove*.
- *Oral commissure*—it is the angle where the upper and lower lip meets.
- *Philtrum*—the upper lip includes the *philtrum*, a midline depression, which can be followed to the nose.
- *Content*—each lip mainly consists of bundles of striated muscle, orbicularis oris, superficial fascia and sub-mucosa. The skin of the lip contains sweat glands, hair and sebaceous gland. The dermal papillae are numerous, with rich capillary supply, which produce reddish pink color of the lips.
- *Vermilion zone*—it is the transitional zone between the skin and the mucous membrane. The vermilion zone contains no hair or sweat glands and contains a few sebaceous glands. In some people, sebaceous glands may be seen as creamy yellow dots. Fordyce's spots along the border between vermilion border and the oral mucosa can also occur.
- *Blood supply of lips*—submental artery to the lower lip and inferior and superior labial arteries to the upper lip.

- *Venous drainage*—anterior facial vein and its branches corresponding to the facial artery provides the venous drainage of lips.
- *Lymphatic drainage*—from central part of lower lip, lymphatics drain to the submental node and rest of the lip to submandibular nodes.
- *Nerve supply*—mental nerve and superior labial nerve.

Developmental Disorders of Lip

Congenital Lip Pits

It is also called as '*paramedian lip pit or congenital fistula*'.

Etiopathogenesis

- *Hereditary*—it is inherited as an autosomal dominant trait.
- *Notching of lip*—there is notching of lips at an early stage of development with fixation of tissues at the base of the notch.
- *Incomplete union*—it may occur due to failure of complete union of embryonic sulci of the lip, resulting in persistent lateral sulci on the embryonic mandibular arch.

Clinical Features

- *Sex predilection*—it is more commonly seen in females.
- *Site*—it is common on vermilion border of either side of midline. It is most commonly seen on lower lip. Lip pits or fistula is unilateral or bilateral depression.
- *Size*—it may be upto 3-4 mm in diameter and may extend as deep as 2 cm.
- *Appearance*—lips, some times appear swollen, accentuating the appearance of the pit.
- *Palpation*—on palpation, sparse mucus secretion may be visible from the base of the lip-pit which occurs due to involvement of underlying minor salivary glands.
- *Syndromes associated*—congenital lip pits may occur in association with *Van der Woude's syndrome* (cleft lip, cleft palate and congenital lip pits). Another syndrome is associated with it is *popliteal pterygium syndrome* which also includes Popliteal webbing (pterygia), cleft lip/cleft palate, genital abnormalities and congenital bands connecting the upper and lower jaws (syngnathia).

Diagnosis

Clinical diagnosis—unilateral or bilateral depression on vermilion border of lip will diagnose these conditions.

Management

- *Surgical excision*—it is done for cosmetic purpose.

Commissural Pits

Commissural lip pits are mucosal invagination occurring at the vermilion border of lip.

Pathogenesis

They occur due to failure of normal fusion of embryonal maxillary and mandibular processes. It is transmitted as autosomal dominant transmission.

Clinical Features

- *Sex distribution*—it is more common amongst males and black people are affected more than white people.
- *Site*—if it is unilateral, it occurs on the right side of the lip.
- *Appearance*—commissural pit appears as a unilateral or bilateral pit at the corner of the mouth on the vermilion surface.
- *Size*—size ranges from a shallow dimple to a tract measuring 4 mm in length and tissue slightly raised above the opening.
- *Palpation*—in squeezing of the lip pit, small amount of saliva can come out.

Differential Diagnosis

- *Congenital lip pit*—it may be associated with facial or palatal cleft.

Management

- *Surgical excision*—it is indicated only in severe condition, where salivary secretion excessive and secondary infection can occur.

Double Lip

It is an anomaly characterized by a fold of excess tissue on the inner mucosal surface of the lip. It may be congenital or acquired because of trauma to the lip.

Pathogenesis

It occurs in 2nd or 3rd week of gestation due to persistent of the sulcus between the pars glabrosa and pars villosa of the lip.

Clinical Features

- *Site*—it usually occurs on inner aspect of upper lip.
- *Cupid bow appearance*—when upper lip is tensed, double lip resembles '*cupid bow*'.
- *Syndromes associated*—it is associated with Ascher's syndrome which consists of double lip, blepharochalasis (it is drooping of the tissue between eyebrow and edge of the upper eyelid so that it hangs loosely over the margin of the lid) and non-toxic thyroid enlargement.

Diagnosis

- *Clinical diagnosis*—cupid bow appearance is typical.

Management

- Surgical excision.

Cleft Lip and Cleft Palate

It occurs along many planes as a result of fault or defect in the development.

Definition

Cleft lip—it is a birth defect that results in a unilateral or bilateral opening in the upper lip between the mouth and the nose. It is also called as harelip. It is wedge shaped defect resulting from failure of two parts of the lip to fuse into a single structure.

Cleft palate—cleft palate is a birth defect characterized by an opening in the roof of the mouth caused by a lack of tissue development.

Development of Cleft

In general, patients with clefts have a deficiency of tissue and not merely a displacement of normal tissue.

- *Unilateral cleft lip*—A cleft lip occurs when an epithelial bridge fails, due to lack of mesodermal delivery and its proliferation from the maxillary and nasal processes. It results from failure of maxillary process on one side to meet and fuse with medial nasal process. This will lead into the division of lip into medial and lateral part. It again occurs due to absence or deficiency of mesodermal masses or their failure to penetrate the ectodermal grooves lead to breakdown of the ectoderm, causing cleft formation. In unilateral cleft lip, the floor of the nose communicates freely with the oral cavity, maxilla on the cleft side is hypoplastic, columella is displaced to the normal side and the nasal ala on the cleft side is laterally, posteriorly and inferiorly displaced.
- *Bilateral cleft lip*—in this, medial mass interposed between two maxillary processes grows down from lateral areas form above the maxillary process. In bilateral cleft lip, the central portion of the alveolar arch is rotated anteriorly and superiorly.
- *Median cleft lip*—it results from partial and complete failure of the medial nasal process to merge. The cleft of lip occurs earlier and inhibits tongue migration, which may then prevent horizontal alignment and fusion of the palatal shelves.
- *Median cleft of mandibular lip*—it occurs due to failure of mesenchymal masses of mandibular process to merge together at 5 weeks of intrauterine life.

- *Cleft of primary palate*—Clefts of the primary palate occur anterior to the incisive foramen. Clefts of the secondary palate are due to lack of fusion of the palatal shelves and always occurs posterior to the incisive foramen. Cleft palate occurs due to disturbances in normal fusion of palatal shelves. This may occur due to failure to unite due to lack of force, interference by the tongue or a disparity in the size of parts involved. It results from failure of the lateral palatine process to meet and fuse with median palatine process. In palatal clefts, the muscles of soft palate are hypoplastic and insert in the posterior margin of the remaining hard palate rather than the midline raphe.
- *Cleft of secondary palate*—The secondary palate closes one week later in females, which may explain why isolated clefts of the secondary palate are more common in females. These are clefts posterior to the incisive foramen. They result of partial or complete failure lateral palatine process to meet, fuse and merge with each other.
- *Cleft of primary and secondary palate*—they result of failure of growth or lack of fusion of three palatine processes with nasal septum and each other.

Etiology

- *Hereditary*—it is one of most important factors to be considered in the etiology.
- *Genetic*—the main possible mode of transmission is by a single mutant gene; producing a large effect or by number of genes (polygenic inheritance), each producing small effects which together create this condition.
- *Nutritional disturbances*—riboflavin deficient diet can produce cleft palate and cleft lip.
- *Developmental*—physiological, emotional and traumatic stress during developmental stages.
- *Defective vascular supply*—defective vascular supply to the area may lead to ischemia which in turn may lead to cleft formation.
- *Mechanical disturbances*—here, the size of tongue may prevent union of the parts.
- *Infection*—infection and lack of inherent developmental force.
- *Miscellaneous*—steroid therapy during pregnancy, alcohol, toxins in the circulation.

Classification

First Classification

- Unilateral incomplete.
- Unilateral complete.
- Bilateral incomplete.
- Bilateral complete.

Second by Veau's

- *Cleft lip*
 - *Class I*—A unilateral notching of vermilion border and it is not extending into the lip.

- *Class II*—a unilateral notching of vermilion with cleft extending into lip but not including the floor of the nose.
- *Class III*—a unilateral cleft of vermilion extending into the floor of the nose.
- *Class IV*—any bilateral cleft of the lip, whether this is complete or incomplete.
- *Cleft palate*
 - *Class I*—involving only soft palate.
 - *Class II*—involving soft and hard palate but not alveolus.
 - *Class III*—involving soft and hard palate and alveolus of one side.
 - *Class IV*—involving both the soft and hard palate and alveolus on both sides of the pre-maxilla.

Third by Kernahan and Stark

- Unilateral incomplete cleft of the primary palate.
- Complete cleft of primary palate ending at the incisive foramen.
- Bilateral complete cleft of the primary palate.
- Incomplete isolated cleft of the secondary palate.
- Complete cleft of the secondary palate—soft and hard palate.
- Unilateral complete cleft of the primary and secondary palate.
- Bilateral complete cleft of the primary and secondary palate.
- Incomplete cleft of the primary palate and incomplete cleft of the secondary palate.

Clinical Features

General

- *Sex*—it is more common in males as compared to females. But incidence of isolated cleft palate is seen more in females.
- *Site*—it is more frequently seen on the left side than on the right side. Left side is involved in 70% of the cases. Cleft of mandibular lip or jaws are rare.
- *Appearance*—a typical patient with cleft palate, cleft lip and ridge exhibits a large defect with a direct opening in the nasal cavity (**Fig. 23-1**).
- *Teeth*—disturbances in the dental structures are seen in this region so that teeth may be missing, deformed, displaced or divided, thus producing supernumerary teeth.

Cleft lip

- There is nasal distortion as lip and nasal tissue pulls towards the attached side.
- *Hare lip*—this term is used to apply for only median cleft lip. Hare lip is derived from the rabbit who normally have cleft in the middle of their lip.

Fig. 23-1: Unilateral cleft lip also involving the cleft palate.

- *Unilateral cleft lip*—a unilateral cleft involves only one side of the lip (**Figs 23-2A and B**).
- *Bilateral cleft lip*—cleft lip is present on the both sides of the midline (**Figs 23-3A and B**).

Figs 23-2A and B: Unilateral cleft lip present on the left side of upper lip.

Figs 23-3A and B: Bilateral cleft lip seen in child patient.

- *Incomplete cleft lip*—it extends for varying distances forward to the nostril, but not upto the nostril (**Fig. 23-4**). The upper part of lip has fused normally.
- *Complete cleft lip*—it extends into nostril and palate is commonly involved. It is often associated with flattening and widening of the nostril of the affected side (**Figs 23-5 and 23-6**).
- *Symptoms*—patient may be presented with difficulty in sucking. Patient also noticed defective speech particularly with the labial letters B, F, M, P and V.
- *Effect on tongue*—there is soft tissue mass between the ends of the bone, uniting the tongue to the lip, so that tongue is bound down.

Cleft palate

- *Site*—there may be cleft of the hard and soft palate or in some cases, cleft of soft palate alone. Entire pre-maxillary

Fig. 23-4: Incomplete cleft lip present on right side which is not extending upto to nostril.

Fig 23-5: Complete cleft lip extending upto nostril.

Fig. 23-6: Complete cleft lip which extends towards the palate.

portion of bone may be missing and in such instances, the cleft appears to be entirely a midline defect.

- *Extent*—cleft of palate may also vary in severity, involving uvula or soft palate (**Fig. 23-7**) or extending all the way through the palate (**Fig. 23-8**) and indirectly to the alveolar ridge on one or both sides (**Fig. 23-9**).

Fig. 23-7: Cleft palate extending all the way towards the palate.

Fig. 23-8: Cleft of palate showing involvement of hard and soft palate.

- *Symptoms*—eating and drinking are difficult due to regurgitation of food and liquid through the nose. Speech problem is serious and tends to increase due to mental trauma.
- *Defect in smelling*—it is due to contamination of the nasal mucous membrane with the oral organism through the cleft palate.
- *Teeth*—the alveolar cleft interferes with the dental lamina. This will result in small upper lateral incisors, absent or even duplicate. Cross bite due to medial collapse of pre-maxilla.

Fig. 23-9: Cleft palate extending to the alveolar ridge

- *Associated anomalies*—isolated cleft palate is associated with other developmental abnormalities like congenital heart disease, polydactyly and syndactyly, hydrocephalus, microcephalus, clubfoot, supernumerary ear, spina bifida, hypertelorism and mental deficiency. Airway problems may arise in children with cleft palates, especially those with concomitant structural or functional anomalies.
- *Syndrome associated*—most common syndrome associated is Pierre-Robin syndrome is the combination of micrognathia, cleft palate and glossoptosis. Affected patients may develop airway distress from their tongue becoming lodged in the palatal defect. Other syndromes which can be present are Goldenhar syndrome, median cleft face syndrome, oral facial digital syndrome, Pert's syndrome, Nagar syndrome, otopalatodigital syndrome, Down's syndrome, and Marfan's syndrome.

Radiographic Features

- It will determine presence and absence of unerupted teeth. The most common missing teeth are maxillary lateral incisors. There is also presence of supernumerary teeth. Teeth are malformed and poorly positioned.
- There is also malposition of the teeth in the region of cleft or in the whole maxilla.
- It will reveal the extent of osseous deformity. There may be complete separation of the premaxilla and maxilla.

Diagnosis

- *Clinical diagnosis*—cleft can be seen clinically on lip and palate.
- *Radiological diagnosis*—cleft palate involving alveolus is seen clearly on radiography.

Management

The complete rehabilitation of the condition requires a multi-disciplinary approach.

- **Cheiloplasty**—it is surgical closure of the lip. A general 'rule of tens' is used in determining optimal timing of lip closure, i.e. 10 weeks of age, 10 pounds of body weight and 10 gm of Hb. At the time of lip closure, when an infant is under general anesthesia, an impression is made for the new obturator.
- **Obturator**—between 3rd and 9th months of age, an obturator is used to provide cross-arch stability, support and to prevent collapse of maxillary arch.
- **Palatoplasty**—it is performed to close an opening in the palate. Surgeons may close the palate in one surgery, when the child is about one year of age or the palate may be closed in two stages, the soft palate is closed first followed by the hard palate.
- **Bone grafting**—sometimes, closure of palatal cleft may be done by bone grafting.
- **Orthodontic therapy**—orthodontic therapy is done to correct malocclusion.
- **Cleft rhinoplasty**—to improve nasal function and correct the distortion.
- **Speech therapy**—speech therapy is given to improve pronunciation of the words.
- **Psychotherapy**—psychological management is necessary.
- **Feeding plate**—to overcome initial feeding problems, feeding plate is used which acts as an obturator to prevent nasal reflux.

Cheilitis

It is inflammation of lip. Various types of cheilitis are described below.

Glandular Cheilitis

It is also called as *cheilitis glandularis*. It is an uncommon condition in which lower lip becomes enlarged, firm and finally everted.

Etiology

- **Sun exposure**—glandular cheilitis can occur due to chronic exposure to sun.
- **Hereditary**—familial occurrence, suggesting a hereditary pattern is also present in glandular cheilitis.
- **Salivary gland inflammation**—inflammation of enlarged heterotopic salivary glands can also be causative factors.
- **Others**—dust, tobacco use and emotional disturbances also been reported in this patients.

Types (Historical)

- **Simple**—multiple, painless, pinhead sized lesions with central depression and dilated canals are present.
- **Superficial suppurative type** (Baelz's disease)—it is characterized by painless swelling, induration, crusting and superficial ulceration of lip.

- **Deep suppurative type** (*cheilitis glandularis apostematosa*, *myxadenitis labialis*)—deep seated infection with abscess and fistula tract that eventually forms a scar.

Clinical Features

- **Age**—it is more common in adults but sometimes, it can also occur in children.
- **Site**—lower lip is involved more often than the upper lip.
- **Symptoms**—enlargement of labial salivary glands occurs which can be nodular.
- **Signs**—orifices of secretory ducts are inflamed and dilated appearing as small red macules over the mucosa.
- **Palpation**—viscid mucous secretion may seep from these openings of everted hypertrophic lips after pressure given on the lip.
- **Volkmann's cheilitis**—it is more severe suppurative form of glandular cheilitis. The lip is considerably and permanently enlarged and is subjected to episodes of pain, tenderness and increased enlargement. The surface is covered by crust (**Fig. 23-10**) and scales beneath which the salivary duct orifice may be discovered.

Fig. 23-10: Severe form of glandular cheilitis showing crust formation

- **Malignant transformation**—it is apparently pre-malignant and epidermoid carcinoma can be associated with it in 18 to 35% of cases.

Diagnosis

- **Clinical diagnosis**—everted hypertrophic lip with secretion after pressure on lip.

Management

- **Vermilionectomy or lip shave**—due to high incidence of associated malignancy, a vermillionectomy or surgical stripping of lips has been recommended. It will give satisfactory cosmetic results.
- **Surgical excision**—if the lips are grossly enlarged, excision of an elongated ellipse of tissue may be required.

Granulomatous Cheilitis or Orofacial Granulomatosis

It is also called as '*Miescher's syndrome*' or '*cheilitis granulomatosa*'. This condition is described in 1945 by Miescher. It is a condition of unknown etiology that is not related to cheilitis glandularis except by the similarity in the clinical appearance of the two diseases.

Etiology

Local causes

- Chronic oral/dental infection
- Embedded foreign material
- Allergy to cosmetics, foods, oral hygiene products and dental restorative materials.

Systemic causes

- Chronic granulomatous disease
- Crohn's disease
- Sarcoidosis
- Tuberculosis

Clinical Features

- *Age and sex*—it is seen in adults as well as in children and there is female predilection.
- *Symptoms*
 - There is diffuse swelling of the lips, especially the lower lip (**Fig. 23-11**).
 - In some cases, an attack is accompanied by fever and mild constitutional symptoms including headache and even visual disturbances.
 - Enlarged lip can create cosmetic problems, difficulty during eating, drinking or speaking.

Fig. 23-11: Diffuse swelling of lower lip in case cheilitis granulomatosis.

- *Signs*—in some cases, scaling, fissuring and vesicles or pustules have been reported.
- *Palpation*—the swelling is usually soft and exhibits no pitting on pressure. Swelling eventually becomes firmer and acquires the consistency of that of hard rubber.
- *Lymph nodes*—the regional lymph nodes are enlarged in some cases, but not always.
- *Skin*—the skin and adjacent mucosa may be of normal color or erythematous.
- *Syndrome*—it is associated with *Melkersson Rosenthal syndrome* which consists of fissured tongue and facial paralysis.

Diagnosis

- *Clinical diagnosis*—soft swelling of lip with fever, headache and vesicle can be seen.

Differential Diagnosis

- *Cheilitis glandularis*—in this condition there is involvement of labial salivary gland.
- *Angioedema*—it is recurrent condition and swelling subsides after giving antihistaminic.
- *Sarcoidosis*—symptoms of fatigue and lethargy are present.
- *Crohn's disease*—gastrointestinal symptoms are present in this case.
- *Lymphangioma*—it is congenital lesion.

Management

- *Corticosteroid injection*—repeated injection of triamcinolone into the lips every few weeks may be effective. Before giving steroids, topical anesthetics gels was applied over the lesion and then 0.1% of triamcinolone acetonide injection is given. This injection should be given weekly for 7 to 10 weeks.
- *Cheiloplasty*—surgical stripping of lip can be done.

Angular Cheilitis

It is also called as '*Perleche*', '*Angular cheilosis*' '*Cheilocandidiasis*'.

Causes

- *Microorganisms*—particularly candida albicans, but also staphylococci and streptococci.
- *Mechanical factors*—overclosure of jaws such as in edentulous patients or in patients with artificial dentures which lack proper vertical dimensions. In it, folds are produced at the corners of the mouth in which saliva tends to collect and the skin becomes macerated, fissured and secondarily infected. Prognathism may give rise to a similar state of affair in young. The recurrent trauma from dental flossing may occasionally be also implicated.

- *Nutritional deficiency*—it can also occur due to riboflavin, folate and iron deficiency with a superimposed fungal or bacterial infection. General protein deficiency can also cause cheilitis.
- *Diseases of skin*—atopic dermatitis involving the face is often associated with angular cheilitis. The incidence also appears to be increased in seborrhoeic dermatitis.
- *Other factors*—hypersalivation, Down's syndrome, large tongue and constant dribbling being the contributory factors. A rare cause is the presence of a sinus of developmental origin at the angles of the mouth.

Clinical Features

- *Age*—it occurs in young children as well as in adults.
- *Symptoms*—it is characterized by feeling of dryness and a burning sensation at the corners of the mouth.
- *Appearance*—it is usually a roughly triangular area of erythema (**Figs 23-12A and B**) and edema at one or more, commonly both the angles of mouth.
- *Signs*—epithelium at the commissures appears wrinkled and somewhat macerated (**Fig. 23-13**). In time, wrinkling becomes more pronounced to form one or more deep fissures or cracks which appear ulcerated but do not tend to bleed, although a superficial exudative crust may form.

Figs 23-12A and B: Triangular area of erythema seen at the angle of mouth in angular cheilitis.

Fig. 23-13: Macerated lesion seen in angular cheilitis.

- *Rhagades*—linear furrow or fissures radiating from the angle of mouth (rhagades) are seen in more severe forms, especially in denture wearers.
- *Prognosis*—if the lesion is not treated, they often show a tendency for spontaneous remission.

Diagnosis

- *Clinical diagnosis*—triangular area or erythema with wrinkled macerated mucosa at angle of mouth.

Management

- *Removal of the cause*—underlying primary cause should be identified and treated.
- *Nutritional supplement*—a course of vitamin B and iron supplements are useful in these cases.
- *Fusidic acid ointment*—it is used in staphylococcal infection. The lesions should be swabbed first and then fusidic acid ointment or cream should be applied at least four times a day.
- *Miconazole*—miconazole may be preferred, if angular cheilitis is due to candidiasis (cream applied locally together with an oral gel).
- *Gentian violet application*—in some cases, it is useful.

Eczematous Cheilitis

The lips are involved secondary to atopic eczema but possibility of contact dermatitis must also be considered. The management of atopic eczema of the lips is with emollient and topical steroids.

Contact Cheilitis

Definition

Contact cheilitis is an inflammatory reaction of the lips provoked by the irritants or sensitizing action of chemical agents in direct contact with them.

Causes

- **Lipsticks**—they are composed of mineral oils and waxes which form the stick; castor oil as a solvent for the dyes, lanolin as an emollient preservative, perfumes and color. The color includes azo dyes and eosin, which is a bromofluorescein derivative. Sunscreen applied in the form of lipstick can also cause contact cheilitis.
- **Lipsalves and other medicaments**—lipsalves containing lanolin are frequently applied for dryness or chapping. Phenyl salicylates and antibiotics have also been incriminated as a cause of cheilitis.
- **Mouthwashes and dentifrices**—essential oils such as peppermint, cinnamon, clove, spearmint and bactericidal agents can cause cheilitis. Propolis, derived from resin and collected by bees, is a well known sensitizer which has been used in toothpastes.
- **Dental preparations**—mercury and eugenol may cause cheilitis in the absence of stomatitis. Allergy to epimine containing materials used for crowns and bridges can cause cheilitis.
- **Foods**—oranges, mangoes and artichokes are among the food plants which occasionally cause allergic cheilitis and dermatitis of the skin around the lips.
- **Miscellaneous objects**—metal hair clips, metal pencils, cobalt paint on blue pencil can also cause cheilitis.

Clinical Features

- **Site**—lipstick cheilitis is usually confined to the vermillion borders but more often extends beyond that.
- **Signs and symptoms**—there may be persistent irritation and scaling or a more acute reaction with edema and vesiculation (**Fig. 23-14**).

Diagnosis

If acute eczematous changes are obviously present, the diagnosis of contact cheilitis presents no difficulty. If an allergic reaction is suspected, patch test can be carried out.

Management

Topical steroids will give symptomatic relief but the offending substance must be traced and avoided. Most commonly used topical steroids use is 1% triamcinolone acetone.

Fig. 23-14: Contact cheilitis occur due to lipstick showing edema.

Actinic Cheilitis

It is also called as *Actinic cheilosis*. Some other terms which use are *Farmer's lips* or *Sailor's lip* as these people are more exposing to sunlight.

Definition

It is a pre-malignant squamous cell lesion resulting from long-term exposure to solar radiation and may be found at the vermillion border of lip as well as other sun exposed surfaces.

Etiology

- **Chronic sun exposure**—it is the main cause, so it usually occurs in hot, dry regions, in outdoor workers and in fair skinned people.

Clinical Features

- **Site**—the lower lip is more commonly affected than the upper lip as it receives more solar radiation than the upper lip.
- **Age and sex distribution**—it is more commonly seen in adult's patient. It is less common in females due to sunscreen effect of lipstick and less common in blacks due to protective effect of melanin.
- **Signs**—in the early stages, there may be redness and edema but later on, the lips become dry and scaly (**Fig. 23-15**). If scales are removed at this stage, tiny bleeding points are revealed. With the passage of time, these scales become thick and horny with distinct edges. Patient can remove scales but it again reforms within few days. Epithelium becomes palpably thickened with small grayish white plaques. Vertical fissuring and crusting occurs, particularly in the cold weather.
- **Margin**—there is blurring of the margin between vermillion zone and cutaneous portion of lip.

Fig. 23-15: Dryness and scaly nature of patient in actinic cheilitis.

- *Superficial erosion*—at times, vesicle may appear which rupture to form superficial erosions (Fig. 23-16). Secondary infection may occur.
- *Nodule formation*—eventually warty nodules may form which tend to vary in size with fluctuation in the degree of edema and inflammation.

Fig. 23-16: Actinic cheilitis showing ulceration of upper lip in female patient.

- *Signs of malignant transformation*—the possibility of malignancy must always be considered if following features are present;
 - Ulceration in actinic cheilitis.
 - A red and white blotchy appearance with an indistinct vermilion border.
 - Generalized atrophy or focal areas of whitish thickening.
 - Persistent flaking and crusting.
 - Indurations at the base of keratotic lesion.

Diagnosis

- *Clinical diagnosis*—redness, edema with history of chronic sun exposure will give clue to diagnosis.

Management

- *Topical fluorouracil*—for mild cases, application of 5% fluorouracil three times daily for 10 days is suitable. It produces brisk erosion but lips heal within 3 weeks. Application of 5-fluorouracil to the lip will produce erythema, vesiculation, erosion ulceration, necrosis and epithelialization. In some cases, podophyllin is also used.
- *CO₂ snow*—rapid freezing with CO₂ snow or liquid nitrogen on swab stick is used to remove superficial lesions.
- *Vermilionectomy (lip shaves)*—under local anesthesia, the vermilion border is excised by a scalpel and closure is then achieved by advancing the labial mucosa to the skin. Postoperative complications include paresthesia, lip pruritis and labial scar tension.
- *Laser ablation*—carbon dioxide laser therapy has been used to vaporize the vermilion. Good results with no postoperative paresthesia or significant scarring have been reported.
- *Electrodesiccation*—it refers to the deeply penetrating tissue dehydration produced by the insertion of electrodes into the tissue.
- *Prevention*—following management, prevention of recurrence by regular use of sunscreen lip salves is advisable. Liquid or gel waterproof preparation containing para-aminobenzoic acid probably gives the best protection.

Exfoliative Cheilitis

It is also called as *Factitious cheilitis*. It is a chronic superficial inflammatory disorder of the vermilion border of lips characterized by persistent scaling and flaking (Fig. 23-17).

Fig. 23-17: Scaling of lip seen exfoliative cheilitis (Courtesy Dr Shetty).

Causes

- *Chronic injury*—these cases may occur due to repeated lip sucking, chewing or other manipulation of the lips.
- *Personality disorders*—emotional disturbance, psychological difficulties and stress can also lead to exfoliative cheilitis.

Clinical Features

- *Age and sex distribution*—age of occurrence is seen in younger group. Most cases occur in girls.
- *Site*—the process starts in the middle of the lower lip and spreads to involve the whole of the lower lip or both the lips.
- *Symptoms*—the patient complains of irritation or burning and can be observed frequently on biting or sucking the lips.
- *Signs*—it consists of scaling and crusting, more or less confined to the vermillion borders and persisting in varying severity for months or years.
- *Perioral skin*—there is erythema of perioral skin

Diagnosis

- *Clinical diagnosis*—Scaling, crusting with perioral skin erythema will aid to diagnosis.

Management

- *Reassurance and psychotherapy*—this is done to overcome personality disorders. After this, many patients get relief.
- *Topical steroids*—hydrocortisone cream is useful in resolving some chronic cases in some patients.
- *Combination*—hydrocortisone can be combined with iodoquinol (antibacterial and antimycotic) cream can be used in chronic cases of exfoliative cheilitis.
- *Others therapy*—it includes topical silver nitrate, salicylic acid, antibacterial and antifungal formulation.

Plasma Cell Cheilitis

It is an idiopathic benign inflammatory condition characterized by dense plasma cell infiltrate in the mucosa close to the body orifice.

Clinical Features

- *Site*—it can affect penis, vulva, lips, buccal mucosa, palate, gingiva, tongue, epiglottis and larynx.
- *Sign*—it presents as circumscribed patches of erythema (Fig. 23-18), usually on the lower lip in elderly persons.

Diagnosis

- *Clinical*—not possible.
- *Laboratory*—on histopathological examination plasma cell can be seen.

Fig. 23-18: Plasma cell cheilitis presenting as erythematous area on lower lip.

Management

It responds to topical application of powerful steroids or to intradermal injection of triamcinolone.

Drug-induced Cheilitis

Hemorrhagic crusting of the lips is a feature of Steven Johnson syndrome which is commonly caused by drugs but, cheilitis can occur as an isolated feature of a drug reaction- either as a result of allergy or a pharmacological effect.

The aromatic retinoids, etretinate and isotretinoin cause dryness and cracking of lips in most patients.

Carcinoma of Lip

Squamous cell carcinoma is the commonest malignancy to affect the vermillion zone. It occurs in light skinned people who have chronic exposure to sunlight.

Clinical Features

- *Age and sex distribution*—there is peak appearance in 6th and 7th decade of life. It is more common in males as compared to females.
- *Site*—it is most common on the lower lips of fair skinned people and persons who work in outer climate.
- *Onset*—it usually begins on vermillion border of the lip to one side of the midline and it may be covered with crust due to absence of saliva.
- *Actinic cheilitis*—it is preceded by actinic cheilitis which is characterized by innocuous looking white plaque on the lip.
- *Symptoms*—patient may complain of difficulty in speech, difficulty in taking food and inability to close the mouth. There is also pain, bleeding and paresthesia.

Fig. 23-19: Induration and ulceration seen at the angle of mouth (Courtesy Dr Suhas Darvekar).

• **Signs**

- It often commences as a small area of thickening, induration and ulceration or irregularity of the surface (**Fig. 23-19**).
- In some cases, it commences as a small warty growth or fissure on the vermilion border of the lip.
- Crater like lesion having a velvety red base and rolled indurated borders.
- As the lesion enlarged, it takes papillary or an ulcerative form.
- In untreated cases, there is total destruction of lip (**Fig. 23-20**) and invasion of cheek, the gums and the mandible.

Fig. 23-20: Total destruction of lip with extensive growth seen in carcinoma of lower lip.

- **Extent**—papillary lesion grows slowly and infiltrated the deeper tissue relatively late whereas ulcerative growth invade early (**Fig. 23-21**).

Fig. 23-21: Extensive lesion of carcinoma of lip showing destruction of mandible.

- **Metastasis**—it may metastasize and it is usually ipsilateral. Carcinoma of the upper lip metastasizes earlier and more frequently than carcinoma of the lower lip. It involves submaxillary and submental nodes first and then deep cervical nodes. Spread by direct extension into surrounding structures and by metastasis which is through lymphatic channels.

Diagnosis

- **Clinical diagnosis**—ulcerative growth with destruction of lip is present.
- **Laboratory diagnosis**—it is mainly well differentiated malignancies.

Management

- **Surgical**—prognosis is good if the treatment is done before metastasis.
- The best results are seen when being obtained when the entire lip mucosal field is removed for early lesion.

Miscellaneous Disorders

Chapping of the Lips

It is a reaction to adverse environmental conditions in which keratin of the vermilion zone loose its plasticity.

- **Causes**—it is caused by exposure to freezing cold or to hot, dry wind, but acute sunburns can cause very similar changes.
- **Clinical features**—lip becomes sore, cracked and scaly (**Fig. 23-22**). The affected subjects tend to lick the lips or to pick at the scales which make conditions worse.
- **Management**—Management is by application of petroleum jelly and avoidance of the causative environmental conditions.

Fig. 23-22: Chapping of lip showing crack in lower lip.

Actinic Elastosis

It is also called as 'Solar elastosis' or 'Senile elastosis'.

Causes

- **Sunlight exposure**—it is caused by prolonged exposure to UV light. UV radiation can produce collagen degeneration in the dermis and extent of this effect is dependent upon factors such as the thickness of stratum corneum, melanin pigment, clothing or chemical sunscreens.

Clinical Features

- **Site**—it is seen on the labial mucosa exposed to sun.
- **Age**—it occurs in elderly population.
- **Signs**—white area of atrophic epithelium develops with underlying scarring of the lamina propria.
- **Appearance**—it includes leathery appearance, laxity with wrinkling and various pigmentary changes.
- **Clinical types**—clinically, it is manifested in three forms:
 - *Cutis rhomboidalis*—thickened skin with furrow giving an appearance of rhomboidal network.
 - *Dubreuilh's elastoma*—diffuse plaque like lesions.
 - *Nodular elastoidosis*—nodular lesion.

Caliber Persistent Artery

A caliber persistent artery is defined as an artery with a diameter larger than normal near a mucosal or external surface. In this condition, main arterial branch extends upto the superficial tissue without reduction in the diameter is present.

Clinical Features

- **Age and sex distribution**—it is more commonly seen in adults as in adults there is loss of tone in the connective tissue.

- **Site**—either lip can involve or some patients have bilateral lesion.
- **Appearance**—the lesion present as linear, arcuate or papular elevation on the lip.
- **Ulcer formation**—such artery in the lip may cause chronic ulceration which can be mistaken for squamous cell carcinoma. The ulcer is attributed to continual pulsation from the large artery running parallel to the surface.
- **Signs**—pulsation can be seen in the lesion. Pulsation is present in lateral direction.

Management

- No treatment is necessary and some time, biopsy is done to avoid the misdiagnosis of the lesion.

Gingival and Periodontal Diseases

Introduction

Gingival and periodontal diseases, in their various forms, have been affecting humans since the dawn of history. Periodontal diseases have been implicated as a major cause of tooth loss besides dental caries.

A review of literature on epidemiology of periodontal disease has concluded that:

- Periodontal disease appears to be a major global public health problem affecting a majority of adult population after the age of 35-40 years.
- The disease starts as gingivitis in young age which, if left untreated, leads to progressive periodontitis.
- More than 90% of the variance of the periodontal severity in the population can be explained by age and oral hygiene.

This concept of periodontitis prevailed until late 1970s. However, the recent studies emphasized on *extent* of the dentition affected by destructive disease (i.e. the percentage of tooth sites involved), and the *severity* of the defects (the amount of lost tissue support). The global distribution of one or several deeper pocket depths (≥ 6 mm) ranged between 1% and 74% in Africa, 8% and 22% in North and South America, 2% and 36% in Eastern Mediterranean, 2% and 40% in Europe, 2% and 64% in South East Asia and 1% and 22% in Western Pacific area.

Normal Periodontium

The periodontium (peri—around, odontos—tooth) consists of gingiva, periodontal ligament, cementum and alveolar bone.

Gingiva

It is the part of the oral mucosa which covers the alveolar process of the jaws and surrounds the neck of the teeth.

The gingiva is divided anatomically into marginal, attached and interdental gingiva.

- *Free gingiva*—the gingiva fits snugly around the teeth, filling each interproximal space between the teeth to the contact area. The gingiva ends in a thin delicate edge called the '*free gingiva*' which is closely adherent to the tooth. The free and attached gingiva blends smoothly with a redder, glossier, unstippled alveolar mucosa of the vestibule and floor of mouth.
- *Color of gingiva*—the color of normal gingiva is a pale coral pink (**Fig. 24-1**) and in the adult the gingiva is dense, firm to touch and insensitive to moderate pressure. It does not bleed easily and it has '*stippled*' or an '*orange peel*' surface.

Fig. 24-1: Normal coral pink color of gingiva.

- *Children gingiva*—in children, gingiva is not stippled and appears redder and more delicate.
- *Interdental tissue*—the interdental tissue in healthy young adults is usually roughly pyramidal in shape, completely filling the space between the teeth almost to the contact area, but there is a small depression or concavity

in the gingival interdental tissue just below the contact area which is called as 'col'. A col lies between the buccal and lingual papillae and is covered with a vestigial structure consisting of epithelial remnants of the enamel organs of the two adjacent teeth.

- **Epithelial attachment**—the most coronal portion of attachment apparatus is called as 'epithelial attachment' or 'epithelial cuff'. It is a band of modified stratified squamous epithelium normally about 0.2 cm in vertical dimension, wrapped around the neck of the erupted teeth in the adults.
- **Fibers of gingiva**—dense fibers of collagen sometimes called as gingival ligament, are seen in gingiva. They are divided into the following groups:
 - **Dentogingival**—it is most numerous groups.
 - **Alveologingival**
 - **Dentoperiosteal**
 - **Circular fibers**—they are small compact group of connective tissue fibers which encircle the teeth. Thus, it helps to maintain the position of the free gingiva.
 - **Transeptal fibers**—they extend from one tooth to other. It is also called as interdental fibers.
- **Blood supply**—it is supplied by vessels of periodontal ligament, supra-periosteal arterioles along the facial and lingual surface of the alveolar bone and arterioles that emerge from the crest of the interdental septa. They are branches of the alveolar arteries and a plexus formed by lingual, buccinator, mental and palatine arteries.
- **Nerve supply**—gingival innervation is derived from fibers arising from nerves in the periodontal ligament and from the labial, buccal and palatal nerve.
- **Venous drainage**—by inferior alveolar vein, posterior superior dental vein and infra-orbital and palatal vein.
- **Lymphatic drainage**—from the upper gingiva passes to the submandibular nodes. Anterior part of the lower gingiva drains into the submental nodes, whereas the posterior part to the submandibular nodes.

Periodontal Ligament

- **Width of periodontal ligament**—the width of periodontal ligament in function is 0.25 to 0.40 mm. Just below the epithelial attachment, there are usually a small number of lymphocytes present.
- **Connective tissue fibers**—a few connective tissue fibers of the periodontal ligament, i.e. the free gingival group fibres project from the cementum of the tooth root into the gingiva without attachment to bone.
- **Composition**—the periodontal ligament is made up of collagen fibers, oxytalan fibers, fibroblasts, amorphous ground substance and interstitial tissue, cementoblasts, osteoblasts and osteoclasts, epithelial rests of Malassez, thin wall blood vessels, lymphatic vessels and tactile sensory nerves.

- **Collagen fibers**—the collagen fibers forming the periodontal ligament are attached to the cementum of the tooth and are inserted into the surrounding tissues. The fibers are arranged in properly defined groups of fibers, also called as principal group. It consists of:
 - **Trans-septal fibers**—it extends interproximally over the alveolar crest and is embedded in the cementum of adjacent teeth.
 - **Alveolar crest fibers**—they are attached coronally, to cementum and at an apical level in bone.
 - **Horizontal fibers**—it runs horizontally from cementum to bone in the same level.
 - **Oblique fibers**—they run from bone, coronally to cementum, apically.
 - **Apical fibers**—from apex of tooth in the bone.
 - **Inter-radicular fibers**—it runs from inter-radicular area of tooth to inter-radicular septa of bone. Seen only in furcated teeth.
- **Frenum attachment**—there are different types of frenum attachment which is described as follows:
 - **Type I**—frenum attached at mucogingival junction.
 - **Type II**—frenum attached in the attached gingiva but not extending till the papilla (**Fig. 24-2**).
 - **Type III**—frenum attached to the papilla, but not extending upto palatal or lingual surface (**Fig. 24-3**).
 - **Type IV**—frenum crosses the papilla and attached to the papilla of lingual or palatal surface (**Fig. 24-4**).

Alveolar Process

It is the portion of maxilla and mandible that forms and supports the tooth sockets. It is formed with eruption of tooth. It provides an osseous attachment to the forming periodontal ligament and disappears after the tooth is lost.

Alveolar process may be defined as the part of the maxilla and mandible that forms and support the socket of the teeth. It is made up of alveolar bone proper, cribriform

Fig. 24-2: Type II frenum attachment.

Fig. 24-3: Type III frenum attachment.

Fig. 24-4: Type IV frenum attachment.

plate and supporting alveolar bone. The latter, in turn, consists of cortical plate which forms the outer and inner plates of alveolar processes and spongy bone which fills the area between these plates and alveolar bone proper.

Alveolar crest is covered with a thin layer of cortical bone and lies within 1 to 1.5 mm of cemento-enamel junction of adjacent teeth. In posterior teeth, alveolar crest is parallel to the cemento-enamel junction. Alveolar crest is continuous with lamina dura with a sharp angle.

Disease of Gingiva and Periodontium

The recent classification for diseases and conditions affecting periodontium was defined by the differences in the clinical manifestations of diseases and conditions. It was the outcome of the consensus opinion arrived at the International Workshop organized by the American Academy of Periodontology in 1999 (Table 24-1).

Table 24-1: Classification of periodontal diseases and conditions

<i>Gingival diseases</i>
<i>Dental plaque-induced gingival diseases*</i>
<i>Non-plaque-induced gingival lesions</i>
<i>Chronic periodontitis**</i>
<i>Localized</i>
<i>Generalized</i>
<i>Aggressive periodontitis**</i>
<i>Localized</i>
<i>Generalized</i>
<i>Periodontitis as a manifestation of systemic diseases</i>
<i>Necrotizing periodontal disease</i>
<i>Necrotizing ulcerative gingivitis (NUG)</i>
<i>Necrotizing ulcerative periodontitis (NUP)</i>
<i>Abscesses of the periodontium</i>
<i>Gingival abscess</i>
<i>Periodontal abscess</i>
<i>Pericoronal abscess</i>
<i>Periodontitis associated with endodontic lesion</i>
<i>Endodontic-periodontal lesion</i>
<i>Periodontal-endodontic lesion</i>
<i>Combined lesion</i>
<i>Development or acquired deformities and conditions</i>
<i>Localized tooth-related factors that predispose to plaque-induced gingival diseases or periodontitis</i>
<i>Mucogingival deformities and conditions around teeth</i>
<i>Mucogingival deformities and conditions on edentulous ridge</i>
<i>Occlusal trauma</i>

* These diseases may occur on a periodontium with no attachment loss or on a periodontium with attachment loss that is stable and not progressing.

** Localized (< 30% of sites involved) and Generalized (> 30% of sites involved). The severity of disease can be characterized on the basis of the amount of clinical attachment loss (CAL) as follows: Slight = 1 or 2 mm CAL; moderate = 3 or 4 mm CAL; and severe ≥ 5 mm CAL and more.

Gingival Diseases

Hereditary Gingival Fibromatosis or Fibromatosis Gingiva

It is also called as 'Elephantiasis gingivae', 'Congenital macrogingivae'. Hereditary gingival fibromatosis is an uncommon condition characterized by diffuse gingival enlargement (Fig. 24-5), sometimes covering major parts or total tooth surfaces. The enlargement develops irrespective of effective plaque removal.

Hereditary gingival fibromatosis may be an isolated entity or part of a syndrome, associated with other clinical manifestations such as hypertrichosis, mental retardation, and epilepsy, hearing loss, growth retardation and abnormalities of extremities. Most cases are related to an autosomal dominant trait. The most common syndrome of hereditary gingival fibromatosis includes hypertrichosis, epilepsy and mental retardation.

Fig. 24-5: Fibromatosis gingivae showing diffuse overgrowth (Courtesy Dr Parate).

Clinical Features

- **Age**—it may be present at birth or may become apparent with eruption of deciduous or permanent teeth.
- **Appearance**—it is manifested as dense smooth diffuse or nodular overgrowth of gingival tissue of one or both arches that usually occurs at the time of eruption of teeth (**Figs 24-6A and B**). It has a characteristic pebbled surface. In some cases, surface has a nodular appearance.
- **Color**—tissue is of normal or pale color. In some cases, it may appear pink.
- **Consistency**—it is often so firm, leathery and dense that it prevents normal eruption of teeth.
- **Symptoms**—it is not painful and shows no tendency for hemorrhage.
- **Extent**—extent may be such that the crown of fully erupted teeth may be hidden.
- **Significance**—the dense firm gingival swelling results in varying spacing between the teeth and change in profile and facial appearance.
- **Radiological features**—in the radiograph, significant bone loss can be present. At the same time, soft tissue is also visible (**Fig. 24-7**).

Diagnosis

- **Clinical diagnosis**—diffuse fibrous overgrowth is seen clinically and it is readily diagnosed.
- **Laboratory diagnosis**—epithelium is thickened with elongation of rete pegs, although the bulk of the tissue is composed of dense fibrous connective tissue. Bundles of collagen fibers are coarse and show few interspersed fibroblasts or blood vessels.

Figs 24-6A and B: Fibromatosis gingivae preventing eruption of teeth in the oral cavity.

Fig. 24-7: OPG of patient having gingival fibromatosis.

Management

- *Surgical*—surgical removal of excessive tissue with exposure of teeth is necessary. However, recurrences are common.
- *Extraction of teeth*—dramatic improvements in gingival enlargements have been observed following extraction of teeth.

Gingivitis

It is the inflammation of the gingiva.

Pathogenesis of Gingivitis (plaque associated)

There is increase in numbers of normal flora organisms that (*Streptococcus*, *Capnocytophaga*, *Actinomyces*, etc.) grow in the gingival crevice producing toxins that cause an inflammatory reaction in the gums. Plaque accumulates in the crevice resulting in an inflammatory reaction. Complications include development of periodontitis.

Classification

Gingivitis can be classified on the basis of:

- *Course and duration*:
 - *Acute gingivitis*—it is of sudden onset and of short duration and can be painful. A less severe form of acute gingivitis has been termed subacute.
 - *Recurrent gingivitis*—recurrent gingivitis reappears after having been eliminated by treatment or disappearing spontaneously.
 - *Chronic gingivitis*—chronic gingivitis is slow in onset and is of long duration. It is painless unless complicated by acute or subacute exacerbations.
- *Distribution*:
 - *Localized gingivitis*—it is confined to the gingiva of a single tooth or a group of teeth (**Fig. 24-8**).
 - *Generalized gingivitis*—generalized gingivitis involves the entire mouth (**Fig. 24-9**).
 - *Marginal gingivitis*—marginal gingivitis involves the gingival margin and may also involve a portion of the contiguous attached gingiva.
 - *Papillary gingivitis*—papillary gingivitis involves the interdental papilla and often extends into the adjacent portion of the marginal gingiva (**Fig. 24-10**).
 - *Diffuse gingivitis*—diffuse gingivitis involves the gingival margin, the interdental papilla and the attached gingiva.

Stages of Gingivitis

- *Stage I gingivitis* (the initial lesion)—the first manifestation of gingival inflammation is vascular changes, consisting essentially of dilation of capillaries and

Fig. 24-8: Localized gingivitis involving lower anterior region.

Fig. 24-9: Generalized gingivitis showing involvement of entire gingiva.

Fig. 24-10: Papillary gingivitis involving interdental papilla.

increased blood flow. No clinical signs appear in this stage. It occurs within 2-4 days of plaque accumulation.

- *Stage II gingivitis* (the early lesion)—this stage is usually seen following 4-7 days of plaque accumulation. In this stage, clinical signs of erythema appear, mainly owing to the proliferation of capillaries and increased formation of capillary loops between rete pegs or ridges. Bleeding on probing may also be evident.
- *Stage III* (the established lesion) (**Fig. 24-11**)—the lesion develops generally after 14-21 days of plaque accumulation. Blood vessels become engorged (**Fig. 24-12**) and congested, venous return is impaired and blood flow becomes sluggish. The established lesion can be described as moderately to severely inflamed.

Fig. 24-11: Established gingivitis is moderately inflamed.

Fig. 24-12: Stage III gingivitis showing engorgement of blood vessels.

- *Stage IV gingivitis* (the advanced lesion)—the lesion extends into the alveolar bone and known as the phase of periodontal destruction.

Clinical Features of Gingivitis

- *Symptoms*—the earliest symptoms of gingival inflammation are increased gingival fluid production and bleeding from the gingival sulcus on gentle probing.
- *Color*—gingiva becomes redder when there is an increase in vascularization or when the degree of epithelial keratinization is reduced. The color becomes paler when vascularity is reduced and keratinization is increased. The color may be sometimes reddish blue or deep blue, if venous stasis has occurred. The color change starts in the interdental papillae, gingival margins and spreads to the attached gingiva.
- *Consistency*—the consistency of gingiva may be spongy that pits on pressure and there may be marked softness of the gingiva.
- *Enlargement of gingiva*—sometimes in inflammation, there may be gingival enlargement and it may lead to change in the contour of gingiva.

Plaque induced gingivitis without local contributing factors

Characteristic of plaque-induced gingivitis are discussed in Table 24-2.

Table 24-2: Characteristics common to all plaque-induced gingival diseases

- Signs and symptoms are confined to gingiva.
- The presence of dental plaque to initiate or exacerbate the severity of the lesion.
- Clinical signs of inflammation (enlarged gingival contours due to edema or fibrosis, color transition to a red or blue-red hue, elevated sulcular temperature, bleeding upon provocation, increased gingival exudates).
- Clinical signs and symptoms associated with stable attachment levels on a periodontium with no loss of attachment or on a stable but reduced periodontium.
- Reversibility of the disease by removing the etiology(ies).
- Possible role as a precursor of attachment loss around teeth.

Plaque-induced gingivitis with local contributing factors

- *Teeth anomalies*—tooth anomalies such as enamel pearls and cemental tears can modify or predispose to plaque-induced gingival diseases. Enamel pearls are found in 1.1-5.7% of molar teeth and maxillary second molar are most commonly involved.
- *Dental restoration*—subgingival margin of restorations and violation of biologic width can affect the health of adjacent gingival tissue.
- *Root fracture*—root fracture and root perforations during endodontic therapy are associated with inflammation of the gingiva and sometimes, pocket formation due to enhanced plaque accumulation.
- *Cervical root resorption*—cervical root resorption may result in inflammation particularly when a communication is established with the sulcus.

- *Other causes*—other cause like deep bite (**Fig. 24-13**), palatogingival groove (**Fig. 24-14**) and shallow vestibule (**Fig. 24-15**) can also lead to gingival inflammation.

Fig. 24-13: Deep bite causing gingival disease.

Fig. 24-14: Palatogingival groove causing gingival disease.

Fig. 24-15: Shallow vestibule causing gingival disease.

Gingivitis due to systemic factors

- *Puberty associated gingivitis*—it appears to be exaggerated response of gingival tissues towards high levels of hormones, especially estrogens and testosterone, secondary to plaque accumulation.
- *Menstrual cycle associated gingivitis*—although bright red hemorrhagic lesions have been described prior to the onset of menses, clinically detectable changes do not seem to be associated with the menstrual cycle. However, an increase in gingival fluid by 20% has been described in 75% of women during ovulation.
- *Pregnancy-associated gingivitis*—the exaggerated response of gingiva to local factors can often appear during the second trimester and regress upon parturition. The condition can be reversed with suitably high levels of plaque control. Pyogenic granuloma of pregnancy is a localized mass of highly vascularized tissue arising as an exaggerated response to plaque. It commonly arises from the proximal gingival tissues and has a pedunculated base. It may show ulceration of its thin epithelial lining. Bleeding on mastication or spontaneously may be a presenting complaint.
- *Diabetes mellitus-associated gingivitis*—there is evidence that Type I diabetes in children is associated with gingival changes. However, when this type of diabetes is under good control, the gingival inflammation is less exaggerated.
- *Leukemia-associated gingivitis*—the leukemia has been associated with gingival changes including gingival swelling, redness/blueness, sponginess and a glazed appearance. The leukemia most commonly associated with gingival changes is acute myeloid leukemia. Any other condition affecting the platelet deficiency can affect periodontium. Cyclic neutropenia, a condition characterized by fluctuation in neutrophils count with a periodicity of 14-36 days, is associated with oral ulceration and exaggerated gingival response to dental plaque.
- *Drug influence gingivitis*—the increased use of oral contraceptives by postmenopausal women has been associated with a higher incidence of gingival inflammation and development of gingival enlargement. This phenomenon can be reversed by discontinuation of medications.
- *Ascorbic acid deficiency gingivitis*—severe vitamin C deficiency in humans results in scurvy, a disease characterized by hemorrhagic diathesis and retardation of wound healing. The clinical features include bleeding, swollen gums and loosened teeth. Scurvy results in defective formation and maintenance of collagen, retardation or cessation of osteoid formation and impaired osteoblastic function. It is also characterized by increased capillary permeability, susceptibility to

traumatic hemorrhages, hyporeactivity of the contractile elements of the peripheral blood vessels and sluggishness of blood flow.

Management of Gingivitis

- *Removal of local irritant*—the local irritants should be removed at this stage.
- *Plaque control*—thorough plaque control should be done with scaling and polishing.
- *Chlorhexidine mouth wash*—use of chlorhexidine, on a short-term basis.

Plasma Cell Gingivitis

It is also called as 'Atypical gingivostomatitis' or 'Atypical gingivitis'. It is allergic in origin and is caused by some ingredients in chewing gums, dentifrices or various diet components.

Clinical Features

- *Sex*—it is more frequently in women and young adults.
- *Site*—it is located on the oral aspect of the attached gingiva and therefore, differs from plaque induced gingivitis.
- *Symptoms*—patients may complain of a sore and burning mouth, scaling of lips and angular cheilitis.
- *Appearance*—entire free and attached gingiva is edematous, friable, granular, bright red (**Fig. 24-16**) and bleeds on slightest provocation.

Fig. 24-16: Bright red color inflammation seen in plasma cell gingivitis.

Diagnosis

- *Clinical diagnosis*—bright red color inflammation with history of some allergen.
- *Laboratory diagnosis*—lamina propria is infiltrated by plasma cells.

Management

- *Cessation of exposure*—cessation of exposure to allergen resolves the lesion.

Gingival Enlargement

Classification

- *Inflammatory enlargement*—it can be acute or chronic.
- *Drug induced*—may occur due to dilantin, nifedipine or cyclosporine.
- *Combined*—it is combination of (inflammatory + fibrotic).
- *Enlargement due to systemic disease*—many systemic diseases like leukemia, Crohn's disease can cause gingival enlargement.
- *Neoplastic enlargement*—benign and malignant tumor of gingiva can cause enlargement.

Acute Inflammatory Enlargement or Gingival Abscess

It results from bacteria carried deep into the tissue, when a foreign substance such as a toothbrush bristle, a piece of apple core or a lobster shell fragment is forcefully embedded into the gingiva.

Clinical Features

- *Site*—it is limited to the marginal gingiva or the interdental papilla (**Fig. 24-17**).
- *Onset*—it is localized, painful, rapidly expanding lesion that is usually of sudden onset.
- *Appearance*—in early stages, it appears as a red swelling with a smooth, shiny surface. Within 24 to 48 hours, the lesion usually becomes fluctuant and pointed with a surface orifice, from which an exudate may be expressed.
- *Teeth*—the adjacent teeth are sensitive to percussion.

Fig. 24-17: Acute gingival inflammatory enlargement seen in lower anterior region.

Diagnosis

- *Clinical diagnosis*—red swelling with shiny surface associated with pain will give clue to the diagnosis.
- *Laboratory diagnosis*—it consists of a purulent focus in the connective tissue, surrounded by a diffuse infiltration of polymorphonuclear leukocytes, edematous tissue and vascular engorgement.

Management

- *Incision*—after topical anesthetic is applied, the fluctuant area of the lesion is incised with a blade and the incision is gently widened to permit drainage. The area is cleansed with warm water and covered with a gauze pad. After the bleeding stops, patient is instructed to rinse every 2 hours with a glassful of water.

Chronic Inflammatory Enlargement

Etiology

- *Local factors*
 - It can be caused by prolonged exposure to dental plaque, which may occur due to poor oral hygiene (**Fig. 24-18**), abnormal relationship of adjacent and opposing teeth, lack of tooth function, overhanging margins of dental restoration and improperly contoured dental restoration or pontics.
 - Food impaction, irritation from clasps or saddle areas of removable prosthesis and nasal obstruction.
- *Habits*—such as mouth breathing can cause gingival enlargement, which is more common in the anterior region.

Fig. 24-18: Inflammatory gingival enlargement occurs due to calculus and poor oral hygiene.

Clinical Features

- *Site*—the enlargement is generally papillary or marginal and localized or generalized.

- *Appearance*—it originates as a slight ballooning of the interdental papilla or the marginal gingiva. In early stages, it produces a life preserver-like bulge around the involved teeth. It increases in size, until it covers a part of the crown.
- *Color*—lesions may be deep red (**Fig. 24-19**) or bluish red. They are soft and friable, with a smooth shiny surface and tendency to bleed.

Fig. 24-19: Inflammatory enlargement shows deep red in color.

- *Progress*—it progresses slowly and painlessly, unless complicated by acute infection or trauma.
- *Discrete mass*—sometimes, enlargement can occur as a discrete, sessile or pedunculated mass, resembling a tumor (**Fig. 24-20**). They may undergo spontaneous reduction in size, followed by exacerbation and continued enlargement. Painful ulceration, sometimes, occurs between the mass and the adjacent gingiva.

Fig. 24-20: Inflammatory gingival enlargement presented as discrete mass.

Diagnosis

- *Clinical diagnosis*—inflammatory enlargement with ballooning of papilla around the teeth will give clue to diagnosis.
- *Laboratory diagnosis*—there is proliferative features of chronic inflammation. Lesions may contain preponderance of inflammatory cells with vascular engorgement.

Management

- *Removal of local factors*—all the factors which are responsible for enlargement should be removed.
- *Antibiotics*—antibiotics should be given. The most commonly used antibiotics is metronidazole.
- *Flap surgery*—periodontal flap surgery is done if necessary.

Drug Influence Gingival Enlargements

Dilantin Sodium

Dilantin sodium is an anticonvulsant drug, which is used to control of epileptic seizures.

Clinical Features

- *Onset*—gingival hyperplasia may begin as early as two weeks after dilantin therapy.
- *Site*—the hyperplasia is generalized throughout the mouth, but it is most severe in maxillary and mandibular anterior region.
- *Appearance*—the first change noted is a painless bead like enlargement of the gingiva, starting with one or two interdental papillae (**Figs 24-21A and B**). The surface of gingiva shows an increase in stippling and finally, a cauliflower, warty or pebbled surface. As the enlargement increases, the gingival tissue becomes lobulated and clefts are seen between each enlarged gingiva.
- *Palpation*—palpation reveals that the tissue is dense, resilient and insensitive. It shows little tendency to bleed.
- *Significance*—they may develop massively, covering a considerable portion of the crown. They may interfere with occlusion. The presence of an enlargement makes plaque control difficult, resulting in a secondary inflammatory process that complicates the gingival hyperplasia. In hyperplasia associated with Dilantin sodium the presence of dental plaque does not seem to initiate the enlargement. Additional studies have demonstrated that oral hygiene procedures may limit the severity of the lesion but are unable alone to lead to a reversal of the condition.

Figs 24-21A and B: Dilantin-induced gingival enlargement showing bead-like enlargement.

Cyclosporine

It is a potent immunosuppressive agent used to prevent organ transplant rejection and to treat several diseases of autoimmune origin.

Clinical Features

- *Clinically*, it is similar to that induced by Dilantin.
- *Site*—growth starts in the interproximal papillae, more frequently in anterior facial areas, partially covering the crown.
- *Appearance*—the tissue is usually pink, dense and resilient, with stippled or granular surface and little bleeding tendency (**Fig. 24-22**).

Nifedipine

- *Action*—it is a calcium channel blocker that induces direct dilatation of the coronary arteries and arterioles, improving the oxygen supply to the heart muscles. It is used in the treatment of acute and chronic coronary insufficiency.

Fig. 24-22: Drug-induced gingival enlargement showing pink resilient surface due to cyclosporine administration.

- Gingival overgrowth occurs in 20% of the cases. The clinical and histological features are same as seen in Dilantin hyperplasia.

Diagnosis

- *Clinical diagnosis*—enlargement of the gingiva with history of drugs will diagnose the condition (Fig. 24-23).
- *Laboratory diagnosis*—the stratified squamous epithelium covering the tissue is thick and has a thin keratinized layer. The rete pegs are extremely long and thin, sometimes called as 'test tube' pegs, with considerable confluence. Mitotic figures are seldom seen.
